The reasons why CO_2 varies over glacial cycles are not well understood (Shackleton, 2000). Clearly, biospheric variations will lead to CO_2 alteration. One theory implicates the growth of Antarctic sea ice extent during glacial times, which covered a larger portion of the Southern Ocean than at present, as the reason for the inhibition of exchange of CO_2 between the

ocean and atmosphere. Stephens and Keeling (2000) suggested that this process may be responsible for approximately 80% of the total CO_2 drop recorded in atmospheric proxy records during the last glacial.

Whether atmospheric CO_2 leads or lags climate change is crucial to determining its role in the growth and decay of ice

sheets. Unfortunately, ice core analysis is equivocal on this issue. The problem is that deep ice cores in Antarctica lack the accurate dating required to match CO₂ variations to known climate change events recorded elsewhere. Therefore, although the effects of atmospheric CO₂ levels on climate are established, and CO₂ changes lead ice sheet responses to climate change (Shackleton, 2000), it remains unclear whether CO₂ actually forces climate change over glacial cycles or simply enhances it.

Ice Sheet Elevation and Mass Balance

As ice sheets build, the surface elevation at which snow accumulates increases. Ice growth results in an increase in the area of the ice mass above the ELA. A feedback is then set up, whereby the increase in the accumulation zone results in further glacier growth. Steady state is achieved by enhanced ablation (e.g., the southern margin of the Laurentide Ice Sheet) and/or by a reduction in accumulation rate as a consequence of elevation increase (as in east Antarctica today). Such is the climatic effect of ice sheet orography (surface relief of the Earth's subaerial continents) on mass balance that, it has been argued, if the ice sheet on Greenland were taken away, it would probably not regrow to its current size without climate cooling (Huybrechts, 2002). Thus, many contemporary ice masses owe their current form to the former climate conditions that permitted their initial growth.

In the past, some ice sheets were so large that the hypsometry (measurement of the elevation of land above sea level) of the continents on which they lay were modified substantially (e.g., the Laurentide Ice Sheet and North America at the LGM). Atmospheric circulation across such large glaciated regions would have been affected by ice sheet orography, and this may have had climatic and mass balance consequences for regions downstream (Kageyama and Valdes, 2000).

Ocean Circulation and Ice Sheet Growth and Decay

It is highly likely that the ocean circulation system affected glacier mass balance in the past. Today, the North Atlantic provides an important source of heat to Western Europe because warm water flows from the mid-Atlantic northwards (Figure 5). If this flow of water were suppressed, the North Atlantic would cool and the heat supplied to Western Europe would be taken away, resulting in colder conditions over Europe and, hence, a reduction in the ELA of regional glaciers. Conversely, if the northward drift of mid-Antarctic water were enhanced, it might lead to warmer conditions and an increase in the ELA in Europe. Warmer and colder maritime conditions may also be associated with wetter and drier climates, respectively. This may explain why Scandinavian glaciers display a positive mass balance over the past few decades, in contrast to the majority of other ice masses, which have decreased in size due to global warming (Braithwaite, 2002).

Process Complexity and Ice Sheet Fluctuations

There are likely other feedback processes than those listed previously, and many of these will be interactive. Therefore, although glacial–interglacial cycles may be forced by orbital variations, the climate processes that allow ice sheets to grow and decay over these timescales are interrelated and, consequently, complex. Such complexity may help explain the rapid, short-term variations in ice sheet volume that occur during glacial cycles, particularly deglaciation.

Ice sheets add complexity to the processes governing their growth and decay. One reason for this is that ice sheet flow cannot be assumed to be stable. Ice may flow by three processes: ice deformation, basal sliding, and deformation of water-saturated basal sediments. Ice deformation occurs in all ice masses. The other two processes require the ice sheet base to

Figure 5 Schematic diagram of the global ocean circulation system.

be at the pressure melting temperature and can result in fast ice flow. The ice base may be warmed by thickening the ice sheet and/or by increasing the ice flow (as the friction associated with ice flow leads to an additional source of heat to the geothermal flux). Thus, as ice sheets grow while frozen to their beds, the basal temperatures increase until a threshold is reached at which subglacial water is generated. This activates subglacial motion and enhanced ice flow. Next, ablation rates likely increase because more ice will be transferred below the ELA. Subsequently, the ice sheet will thin, resulting in reduced basal temperatures and, eventually, the deactivation of enhanced ice flow. This 'binge-purge' model of ice sheet behavior has been used to explain the short-term rapid flow of the Laurentide Ice Sheet, which oscillated at its southern ablation margin to form a series of 'lobes' and across its eastern margin to periodically issue large numbers of icebergs into the North Atlantic, depositing layers of ice rafted debris, known as Heinrich layers (MacAyeal, 1993; Figure 6).

Periods of enhanced ice flow may be associated with the increased production of both meltwater and icebergs. Each of these leads to the transfer of freshwater from the continent to the ocean. In the case of the Laurentide Ice Sheet, the ocean to which such material is delivered is the North Atlantic, the site of deepwater formation and the engine of the thermohaline circulation. Thus, the short-term periodic enhanced flow of the Laurentide Ice Sheet, associated with the deposition of Heinrich layers, may also be linked with perturbations in ocean flow and, consequently, rapid climate change across the landmasses bordering the North Atlantic. This ice-ocean-atmospheric linkage may be particularly important during deglaciation, and it may have led to large-scale reversals in climate such as the Younger Dryas (Tarasov and Peltier, 2005).

A feature of several ice masses that underwent post-LGM retreat is the accumulation of meltwater across their proglacial regions (Mangerud et al., 2001). During ice sheet decay, many such proglacial lakes would have been extensive. In the case of the Laurentide Ice Sheet, the majority of its southern margin was in contact with huge expanses of proglacial meltwater. One massive lake, Lake Agassiz, grew larger as ice decay continued. Being dammed by the ice, a threshold was reached at ~8.2 ka, at which the ice sheet could no longer hold the lake water, resulting in a catastrophic outburst. So much water flowed to the North Atlantic that the sea-level rose by ~20 cm in a matter of days, according to some researchers, and a brief period of cooling resulted, which is recorded in the Greenland ice core (Barber et al., 1999).

The southern margin of the Eurasian Ice Sheet ~90 ka was also associated with a large proglacial lake named Lake Komi (Mangerud et al., 2001). According to numerical modeling of the ice sheet-climate-lake system, Lake Komi caused a reduction in the level of summer melting across the southern margin of the ice sheet, which supported ice sheet growth and delayed ice sheet decay. In contrast, other proglacial lakes have been found to accelerate ice sheet decay by allowing the process of iceberg calving to contribute to the loss of ice in otherwise terrestrial regions of large ice sheets.

Therefore, it seems likely that proglacial lakes may influence growth and decay of large ice sheets and, if they outburst into the oceans, may lead to rapid short-term oscillations in climate and glacier mass balance.

Figure 6 Binge-purge theory of ice sheet growth and decay. (a) Ice sheet growth occurs on a frozen bed. The only mechanism of ice flow is through ice deformation. (b) Further ice sheet buildup results in basal temperatures reaching the pressure melting point. Basal sliding contributes to ice flow and the ice sheet margin expands. (c) Enhanced velocities lead to more ice being lost to iceberg calving than is replenished through accumulation. The ice sheet issues icebergs and meltwater to the ocean and thins as a consequence. (d) Ice sheet thinning and retreat leads again to frozen basal conditions, slow ice flow, and ice sheet regrowth.

There are several large remnants of the last ice age. Of these, possibly the most important to modern environmental processes is the Greenland Ice Sheet, which is much larger now than in the Eemian interglacial (~125 ka; Cuffey and Marshall, 2000). Processes that have been linked with the decay of large ice sheets, such as the perturbation to the ocean circulation system and the associated rapid environmental change, remain relevant today because this ice sheet in particular reacts to climate warming and issues large volumes of freshwater (via runoff and icebergs) directly into the North Atlantic.

Importance of the Extent of Past Glaciers and Ice Sheets

Reconstruction of past areal and vertical ice extent is important because the volume and the height of ice sheets strongly influence global sea level and patterns of oceanic and atmospheric circulation. Ice sheets are large topographic features that create anomalies in albedo (reflectivity) and radiation balance, and represent significant freshwater reservoirs. They can influence climate by displacing the jet stream, by cooling the air, by reorganizing storm tracks, by releasing freshwater into the ocean, or by changing sea level. Therefore, past vertical and horizontal ice extents are important boundary conditions for paleoclimate modeling. If general circulation models are able to simulate climatic extremes, such as the time of major global glaciation, model-based future predictions will gain greater credibility.

Investigations of past ice extent also help in the understanding of glacial processes such as ice stream behavior (fast-flowing parts of ice sheets, enabled by the presence of large amounts of meltwater at the ice–bed interface). Such knowledge is important for a better prediction of the stability of current ice sheets, especially the West Antarctic Ice Sheet, which ablates dominantly through ice streams. Vertical ice extent in mountainous areas determines the distribution and size of nunataks (mountain tops that rise above the ice surface), and these have been proposed as ice-age refugia for plants and animals.

Areal Ice Extent

Ice Sheets During the Last Glaciation

The vast Laurentide Ice Sheet in North America had several ice domes and divides and was at times partly confluent with the smaller Cordilleran Ice Sheet and with the Innuitian and Greenland Ice Sheets at the Last Glacial Maximum (LGM; between 19 and 23 cal ka BP). In Europe, the Scandinavian (or Fennoscandian) Ice Sheet was the largest ice mass and probably coalesced with the British and Irish Ice Sheets during the time of their maximum extent. From the northern Baltic Sea area, the ice sheet radiated south- and eastward into major and minor ice lobes. Ice complexes in the southern hemisphere included the Patagonian Ice Sheet in South America and the Antarctic Ice Sheet, as well as glaciated areas in southeastern Australia and in Tasmania. Minor ice caps occurred in the tropical/subtropical zone, including East Africa, the Himalayas and the Tibetan Plateau, Japan, Taiwan, New Guinea, New Zealand, the Hawaiian Islands, the tropical Andes (Ecuador, Peru, Bolivia), and the circum-Caribbean region (Mexico, Guatemala, Costa Rica, Colombia, Venezuela).

Detailed Maps of Glacial Extent

The areal extent of Quaternary glaciations has been studied extensively and summarized in numerous publications. While

the ice extent for the LGM is relatively well-known, earlier glaciation limits are more difficult to determine. For the LGM, the nature of Earth's surface has been examined and mapped, and the climate system has been studied within two comprehensive projects: CLIMAP (Climate Long-range Investigation, Mapping, and Prediction; [CLIMAP Project Members, 1981](#)) and EPILOG (Environmental Processes of the Ice Age: Land, Ocean, Glaciers; see special issue of *Quaternary Science Reviews* 21: 2002). A recent overview by [Ehlers and Gibbard \(2004\)](#) comprises three volumes that cover different parts of the world and contain CDs with supporting material (GIS files).

Determination of the Areal Extent of Former Glaciers

The most conspicuous, and earliest recognized, remnants of past ice cover are erratic boulders, large rocks that have been transported by ice far away from the bedrock exposures from which they originated. In the less than 200 years since the recognition that glaciers were much more extensive than they are today, it has become evident that the glacial record is far more complex than this. The glaciers have left behind sediments and landforms, and although they together provide an integrated picture of the nature and extent of former ice sheets, they are discussed separately below.

Sediment record

Glaciers transport sediment on their surface, as debris-rich ice near the bed, and by causing deformation of soft sediment beneath the ice. Typically, glacier-transported sediment is poorly sorted (diamicton) and is called till if deposited directly by the glacier. Although till can be confused with landslide debris or other diamictons, the presence of a variety of lithologies, preferred orientation of clasts, and association with subglacial landforms can generally be used to map the former extent and flow direction of glacial ice. Glacial sediment that accumulates on the ice surface often slides and flows from high to low spots, causing differential melting of the underlying ice. The hummocky topography produced by this process contains a mix of till, debris flow sediment, and stream and pond sediment. Meltwater carries huge amounts of sand and gravel away from the ice margin. This sediment may be deposited far from the ice margin, so it is not a good indicator of ice extent, unless it is clear that the stream sediment was deposited on or under glacial ice (i.e., ice-contact glaciofluvial sediment). Often, signs of collapse of the sediment bedding indicate that ice once lay below, thus providing an indication of former ice extent. Glaciomarine sediments rarely show the former extent of ice but can be an important indicator of glaciation in the geologic record, because marine deposits are more often preserved than terrestrial deposits.

Geomorphological features

As glaciers move, they erode the underlying rock or sediment, and transport it in the direction of ice flow. Most of this sediment is deposited in landforms that vary considerably

depending on, for example, landscape relief, ice thickness, temperature, and presence or lack of water at the glacier bed. Often the nature and distribution of landforms provide a key to glaciological conditions when the landscape formed. One way of classifying these landscapes is by using a landsystems approach. A landsystem is characterized by its specific combination of landforms, subsurface materials, and vegetation types and thus allows the understanding of individual landforms in a broader landscape context. Many different glacial landsystems have been recognized (Evans, 2003); common landform assemblages are described below.

In some areas behind the ice margin, ice sheets erode preglacial soil and weathered and solid rock. Rock surfaces left behind are scoured and sometimes polished and marks indicate the former presence of ice and its flow direction (Figure 1). Pieces of rock or mineral fragments that are incorporated at the glacier base and dragged along leave scratches called glacial striations or striae on the rock surface, probably the most common features left by glacier ice. Deeper marks that are elongate in the direction of ice flow are called glacial grooves.

At places where debris at the ice base chattered over the rock surface instead of moving along smoothly, chatter marks or crescentic fractures develop. Reverse crescentic fractures are concave in an up-ice direction, due to a force applied by a rolling stone on the ice base at the up-ice side of bedrock outcrops. Crag and tail features, left behind by knobs of hard rock protruding from softer rock and thus protecting a tail of the softer rock down-ice from erosion, are valuable indicators of the direction of ice flow.

Larger landforms produced by glacial erosion, especially in alpine areas, provide evidence of the extent of past glaciers. Valleys produced by river downcutting typically have a V-shaped cross-section, whereas U-shaped valleys indicate the former presence of ice (Figure 2). Many of these U-shaped valleys were fed by glaciers in cirques, bowl-shaped basins produced by glacial abrasion and plucking. Often cirque floor elevations are used as one indicator of the position of the former equilibrium line. Rock is commonly gouged more deeply in some places than others, producing depressions that may become lakes. Since stream valleys do not have

Figure 1 Glacial erosional forms on rock surfaces, showing the direction of ice flow. Reproduced from Prest VK (1983) Canada's heritage of glacial features. *Geological Survey of Canada, Miscellaneous Report 28*, with permission.

natural lakes, the presence of shallow rock basins along the valley bottom proves the extent of past glaciers. In places where several cirque glaciers have eroded headward toward a peak, a horn is produced (Figure 3). U-shaped valleys that have their floors below sea level are called fjords (Figure 4), and glaciers that eroded fjords terminated in water, thus producing landform and sediment assemblages different from those described below (Powell, 2003; Vorren, 2003). Sediment is delivered to alpine glaciers by subglacial erosion, and by avalanche and other mass wasting processes on to the ice surface. Many glaciers have accumulations of sediment along their edges called lateral moraines. Their upper extent marks the upper limit of former glacier ice on the valley wall. Where these moraines meet at the confluence of alpine valleys, sediment is carried on to the ice surface and then down-valley. These medial moraines (Figure 2) are rarely preserved after ice has disappeared. End moraines are ridges of sediment that form in the valley away from valley walls. The position of moraines

indicates the extent of glacier ice when the moraine was being formed, and often successive advances produce sequences of moraines that are progressively older down-valley.

Ice sheets that cover generally low-relief and low-elevation areas also leave behind end moraines that mark the extent of ice at the time the moraine was formed (Figure 5). They are characterized by their hummocky topography, and may contain sand and gravel as well as till and supraglacial diamicton. These are the most common landforms used to map the former extent of glacier ice in low, rolling landscapes. The outermost extent of an ice advance is called a terminal moraine, and moraines formed during ice retreat are recessional moraines. These ridges are generally interpreted as representing positions of stability of the ice margin. Moraines can be formed by several processes, including deposition of basal till, collapse of supraglacial sediment, bulldozing and ice shove, and stacking of debris-rich ice layers that may melt out centuries later. These differences in process result in different sizes and forms

Figure 2 Large-scale features produced by glaciation in alpine areas: (a) during glaciation, (b) after deglaciation. Adapted from Strahler AN and Strahler AH (1974) *Introduction to Environmental Science*. Santa Barbara: Hamilton Publishing, with permission.

Figure 4 View of Fjaerlandsfjord, Norway, showing U-shaped valley cross-section.

of moraines. They range from less than a meter high to several tens of meters and from about a meter to several kilometers in width. Although generally composed of diamicton, in some parts of the world some ridges of meltwater-deposited sand and gravel are called moraines. These are often in the shape of coalescing alluvial fans and deltas deposited near the ice margin, and like true moraines, indicate the presence of a stationary ice margin position.

In some environments, the land surface over which the ice rides is streamlined by a combination of erosion and deposition. The resulting elongate hills are called drumlins ([Figure 6](#)), and these can be used to determine the flow direction of former ice masses. Drumlins may indicate not only the extent of glacier ice, but also the conditions at the glacier bed when the streamlining took place. They are generally thought to have been shaped and streamlined when there was water at the bed of the ice and the glacier was sliding. Smaller elongate forms, called flutes, are present on many recently deglaciated surfaces,

but may be difficult to recognize on Pleistocene-age vegetated landscapes. In some subglacial environments, particularly where the bed of the glacier is frozen but wet, soft sediments are present beneath, stresses are propagated into the rock or sediment, and thrust features, called hill-hole pairs or anamoores ([Figure 7](#)), are formed as slabs of frozen sediment or rock are thrust by the glacier.

Associated subglacial meltwater features are tunnel channels and eskers, which are deposited by water flowing beneath the ice. Tunnel channels are primarily stream-cut channels that were partly or wholly filled with meltwater sediment and supraglacial diamicton as ice thinned. They formed in several different subglacial environments, but generally formed in the marginal zones of former ice sheets, perhaps where the base of the glacier was partly frozen to its bed, or where breaking ice dams caused catastrophic flows of subglacial meltwater. Eskers ([Figures 8 and 9](#)) are generally sinuous ridges of gravel that may extend for up to hundreds of kilometers across the

Figure 5 Lowland landform assemblage: (a) during glaciation, (b) after deglaciation. Adapted from Strahler AN and Strahler AH (1974) *Introduction to Environmental Science*. Santa Barbara: Hamilton Publishing, with permission.

landscape. In some areas that were under the thickest parts of ice sheets, and where most sediment has been scoured from bedrock surfaces, eskers provide the clearest record of former glaciation. Stream-deposited sand and gravel accumulates on the glacier surface in places where streams rework sediment from melting debris-rich ice. Collapse of this gravel produces a hummocky surface. Depressions called kettles are produced as the last buried ice melts between hummocks that are sometimes called kames. Water and sediment flowing down a moulin, a vertical shaft in the ice, and accumulating in an inverted cone-shaped hill, produce moulin kames (Figure 10). Where meltwater exited the ice, ice-contact fans or deltas typically formed. In some areas, these are the only indicators of a former ice margin position if no moraine was built. Sand and gravel

plains and terraces may have kettles that demonstrate that ice formerly underlay the surface. In the absence of till, this pitted outwash may be the only indicator of former ice cover.

In areas where the ice margin was against hills at its maximum extent or during deglaciation, lateral meltwater channels commonly mark former ice margin positions. The slopes of the floors of ice-marginal channels indicate the slope of the intersection of ice with the hillside and allow ice extent and ice surface slope to be determined.

In places, ice-marginal lakes can be used to reconstruct previous ice extent even where glacial deposits are lacking. Abandoned beaches and lake outlets can be used to determine the former elevation of ice-dammed lakes. Ice advances typically block outlets, causing lake levels to rise or new lakes to form.

Figure 9 Cross section of Pine River Esker in New Hampshire, USA.

Figure 10 Moulin kame forming at base of moulin beneath marginal zone of the Burroughs Glacier, Alaska, USA. Vegetation and soil has been removed ahead of mining.

Ice retreat often exposes lower outlets, allowing water level to fall or lakes to entirely disappear. Because these lakes require a glacier dam in order to exist, in the past ice must have extended far enough across a landscape to dam the water.

Most of the above features are studied from air photos and field examination. However, some features can only be well displayed with satellite images (Boulton et al., 2001) or digital elevation models of large areas. These provide overviews of glacial bedforms and their succession, and can be used to map maximum ice extent and deglaciation patterns (Clark, 1997). Figure 11 shows a digital elevation model of the southwestern part of the Laurentide Ice Sheet. The extent of glacier ice can be clearly seen. Streamlined paths due to ice flow are interpreted to be indicators of fast-flowing (streaming) ice (Clark and Stokes, 2003).

The above features allow determination of the extent of glacier ice in many locations, but there are places where former ice left little trace of its presence, leading to debates on whether

these regions were glaciated at all. Even in areas where glacier coverage is obvious, there may be debate about whether it was during the last glacial cycle. Determining the age of glaciation is routinely undertaken using radiocarbon dating, but this is limited to the last glaciation and to deposits containing organic matter. When organic material is lacking in glacial deposits, optically stimulated luminescence and cosmogenic radionuclide surface exposure dating techniques are now commonly used to determine the age of glaciation. Weathering rates and degree of soil development can also be used to indicate the relative age of geomorphic surfaces.

Areas of Uncertain Areal Extent

The extent of glaciation is difficult to detect in places where glaciers did little geomorphic work and, therefore, had little effect on the landscape. The absence of till, meltwater stream deposits, or erratics can be interpreted either as a lack of

Figure 11 Shaded relief map of the southwestern part of the Laurentide Ice Sheet in the United States and Canada, showing evidence of ice streaming along the western side of the Laurentide Ice Sheet. The central parts of ice lobes flowed parallel to the axis of the lobes, suggesting stagnant or slow moving ice along the edges of the lobes. Note southwestern extent of the Laurentide Ice Sheet is the line separating unglaciated terrain in the West from glaciated terrain to the East and North. Image by Paul Morin, data from NASA Shuttle Radar Topography Mission. See [Jennings \(2006\)](#) for further information.

glaciation or that the ice that covered the area left no deposit behind – it was clean ice. The presence of paleosols, deeply weathered rock, surfaces covered with weathered boulders, and lack of striations or other erosional features, may also be explained in different ways. Conditions at the bed of glaciers differ considerably. Some have abundant water, and slide or ride on a deforming soft-sediment layer. These readily shape the landscape beneath. In some places, there was little erosion, and thick till was deposited. Other glaciers or parts of glaciers are frozen to their beds. Although some basal movement has been measured even in frozen-bed glaciers, occasionally they appear to have relatively little impact on the underlying ground surface; they do not alter the landscape significantly and can thus preserve relicts from former glaciations and interglacials (as has been inferred for the central Fennoscandian Ice Sheet – [Kleman and Hättestrand, 1999](#); [Stroeven et al., 2002](#)). Examples of regions of debatable areal extent are described in the following text and in more detail by [Rutter \(1995\)](#).

Northern Laurentide Ice Sheet

The limit of the Laurentide Ice Sheet during the last glaciation (the Late Wisconsin) is well-established at its southern border, but remains contentious in many other areas ([Dyke et al., 2002](#)). Ice extent on eastern Baffin Island is still debated. Timing of maximum ice extent is not well-known for the northwestern Laurentide margin. Another debate concerns the coalescence of the Laurentide Ice Sheet with the Cordilleran Ice Sheet. It is now well-established that the two ice sheets coalesced at their southern margin, but at the northern part of their respective borders, an ice-free corridor may have existed. The two ice masses seem to have developed out of phase.

Innuitian Ice Sheet

After much debate as to whether an Innuitian Ice Sheet existed over the northern half of the Canadian Arctic Archipelago during the LGM, consensus has emerged that such an ice sheet covered most of this region, based mainly on evidence from flow and from meltwater features ([Dyke et al., 2002](#)). However, the northwestern limit of this ice mass, presumably located on the polar continental shelf, has not been mapped to date.

Barents Sea

An ice sheet that was centered over the Barents and Kara Seas probably expanded on to mainland Russia several times during the Quaternary, but there has been a long-standing debate about whether it existed during the last glaciation. Northern Eurasia has been studied extensively in the QUEEN program (Quaternary Environments of the Eurasian North; see special volume of *Boreas*, 1999, 28(1)). Glaciologic modeling supports a larger ice sheet that covered parts of the Russian mainland, while most field observations and geochronometric data suggest that the area was not overridden by ice during the last glaciation.

Eastern Siberia

Another debate of ice extent centers on northeastern Siberia. Some evidence for a marine-based ice sheet comes from features identified through sea-floor mapping on the Chukchi shelf, but their age has not been determined. Other studies strongly question the existence of an LGM western Arctic ice sheet ([Sher, 1995](#)).

Antarctic Ice Sheet

Evidence is growing that the West and East Antarctic Ice Sheets did not advance and retreat synchronously. Probably the West Antarctic Ice Sheet extended to the shelf edge in most areas, as has been inferred from geophysical surveys of the Antarctic continental shelf, while the East Antarctic Ice Sheet advanced to a mid-shelf position only.

Tropical and subtropical regions

LGM conditions are still controversial in many parts of the tropics and subtropics. Studies have recently been compiled in a special volume of *Quaternary International*, 2005, 138/139).

Vertical Extent

Determination of Vertical Extent

The vertical extent of former glaciers and ice sheets is much more difficult to determine than the areal extent and involves more uncertainties, because there is often no direct geological proxy available. We outline methods that are commonly applied in order to infer the vertical extent of ice masses, especially for the last glaciation.

Isostatic rebound

The ice-water mass exchange during a glacial cycle is sufficient to generate a deformation of the Earth, called glacial isostatic adjustment. Present rates of uplift in formerly glaciated areas can be used to infer former ice thickness distribution using rheologic modeling. Uplift rates observed relative to mean sea level have to be corrected for eustatic changes. Theoretical tilting of shorelines computed in the models is then compared to observed shoreline tilting. The relative sea-level data might, however, primarily reflect the deglaciation period subsequent to the LGM and hence not give a definitive estimate of LGM ice thickness. Also, these data are confined to coastal regions and, therefore, provide little constraint on ice thickness in interior regions. Furthermore, isostatic modeling often relies on the assumption that the postglacial uplift is caused entirely by unloading due to ice sheet melting. Often, possible tectonic components in the uplift are not considered or are difficult to estimate.

Global sea-level change

The magnitude of global sea-level change due to LGM glaciation has been debated for a long time. The Laurentide and the Fennoscandian Ice Sheets contained the majority of ice at the LGM, but smaller ice sheets and glaciers also contributed to global sea-level lowering. CLIMAP presented two possible ice sheet reconstructions: a minimum model, accounting for 127 m of ice-equivalent sea-level lowering, and a maximum model (with extensive marine-based ice sheets), accounting for 163 m of sea-level lowering (Denton and Hughes, 1981). Subsequently, substantially thinner ice sheets have been inferred, for example, through isostatic modeling, suggesting a global sea-level lowering of about 120 m (Peltier, 2002) to 130–135 m (Lambeck et al., 2002; Milne et al., 2002). Coral reef data also yield sea-level records that suggest a sea-level lowering of about 120 m due to glaciation. Geochemical records of oxygen isotopes ($\delta^{18}\text{O}$) from deep-sea cores provide supporting evidence for the LGM ice volume.

Ice-sheet modeling

Observational control on ice sheet thickness changes remains limited in many areas, for example, the Greenland and the Antarctic Ice Sheets, but also for most parts of the Laurentide Ice Sheet. For these locations, glaciological modeling is especially useful (Marshall et al., 2002; Siebert et al., 2001). Most models applied are time-dependent and thermomechanically coupled and account for isostasy. They are based on mathematical relations of mass balance (resulting from snow accumulation and ice ablation), ice flow, and interaction of the ice with the underlying bedrock. Models use paleoclimatic

information, often as output from paleoclimate models or from proxy data, in order to simulate ice extent and ice thickness evolution over time. Often sensitivity experiments are carried out in which parameters are varied within plausible ranges of uncertainty. Model results are constrained by comparison with the geological data available. However, models are generalizations of reality; not all possible processes are represented in models, and parameterizations are simplifications.

Consolidation measurements

The pressure exerted by an ice mass leads to the vertical compression of the underlying soil. Water and air are expelled from pore space in the sediment, soil particles are packed more closely, and deformation of the soil particles takes place. All these processes yield a volume change that is called consolidation. The stress that has been experienced by a soil sample when it was overridden by ice in the past can be inferred by consolidation testing, during which an increasing load is applied to the sample and the resulting deformation is observed. From changes in the response of the sample to the load, the preconsolidation pressure can be inferred. Since former pore water pressure partially supported the ice load, only minimum ice thickness values can be estimated from the consolidation testing results.

Sources of error for this method include disturbances or changes in the moisture content of the sample during collection or storage, fluctuations in the water table during the geologic history of the sampling area, changes in soil structure by freezing and thawing, or the presence of permafrost or meltwater during maximum ice load.

Landmarks

Geomorphic observations can help to identify upper ice sheet/glacier limits. Indicators used include trimlines, separating an upper zone of *in situ* weathered bedrock and a lower zone of glacial erosion and hence representing the upper limit of glaciation in mountainous areas (Figure 12). However, these landmarks are often controversial for several reasons: They could represent a glacial readvance rather than the maximum vertical ice limit, or periglacial weathering may have taken place after deglaciation, or they may indicate the boundary between frozen and temperate conditions at the ice base. Mineral magnetic soil measurements or soil clay-fraction mineralogy may help to address this problem if reliable dating for bedrock above and below the trimline is not available.

Cosmogenic dating

Cosmogenic nuclides (^{26}Al , ^{36}Cl , ^{10}Be , ^3He , ^{21}Ne) are produced in surface rocks (affecting mostly the upper 1 or 2 m) by cosmic radiation. Samples for cosmogenic dating are often taken from quartz-rich clasts or quartz veins from glacial erratic boulders or from glacially smoothed bedrock. Areas that show signs of weathering or surface degradation have to be avoided. Production rates are used for calculating surface exposure ages after corrections for altitude and latitude. However, some uncertainties arise from possible erosion and/or burial of the surface. Erosion rates are sometimes difficult to estimate.

Figure 12 Photo of trimline between clearly glaciated, till-covered surface below and weathered rock-strewn surface above, Nordfjord, Norway. Photograph by M. Hildreth.

Examples for Controversial Areas of Vertical Ice Extent

Evidence for vertical ice sheet extent is often controversial. For example, ice thickness at the LGM of the Scandinavian Ice Sheet in the mountainous areas in southwestern Norway has long been debated. While ice-free regions in western and northern Norway have been postulated on the basis of biological findings (survival of endemic plant and animal species), geomorphic evidence (presence of steep-sided peaks, cirque topography, summit block fields), and cosmogenic dating, thick ice that covered all mountain peaks has been inferred from numerical modeling of glaciological processes, preconsolidation testing, isostatic response, till fabrics, and striation patterns.

A similar controversy has evolved around glacial extent in eastern Baffin Island, Arctic Canada. While some researchers inferred ice-free refugia and large outlets of Laurentide ice that were restricted to fjords and valleys, others suggested a complete ice cover of Baffin Island during the last glaciation (see overview in [Miller et al., 2002](#)).

As methods of dating improve and we gain a better understanding of how cold-based glaciers function and how to interpret the meager traces they leave behind, these controversies will likely be resolved.

Evidence of Glacier Flow Directions

C R Stokes, Durham University, Durham, UK

Introduction and Significance

Knowledge of the flow direction of Quaternary ice sheets is crucial to both paleoglaciology and glaciology and has important socioeconomic implications in terms of mineral prospecting and mining. In paleoglaciology, evidence of former ice flow directions is a key ingredient for accurate reconstructions of the behavior of former ice sheets. Such reconstructions typically span thousands of years and provide valuable knowledge of how ice sheets evolve and both respond to and perturb the ocean-climate system (e.g., Clark et al., 2010; Kleman et al., 1997). These reconstructions, based on glacial geomorphology, are also required to test numerical models of paleo-ice sheets (e.g., Holmlund and Fastook, 1995; Tarasov and Peltier, 2004) and, significantly, provide a key context for assessing the present stability of modern-day ice sheets and the likely magnitude of sea-level change that might be expected under different climate scenarios (Alley et al., 2005).

Evidence relating to former ice flow directions is also intimately linked to subglacial processes that occur at the base of ice sheets and facilitate their flow. Because of the inaccessibility of modern-day ice sheet beds, these processes are poorly constrained, leaving us with a rather rudimentary understanding of how ice interacts with the underlying substrate and how such processes ought to be parameterized in numerical models of ice flow. It is known, however, that former ice flow directions are recorded by suites of subglacial bedforms (e.g., drumlins) created at the ice-bed interface and these have recently been imaged beneath a West Antarctic ice stream (King et al., 2009). These ice flow indicators are a direct manifestation of subglacial processes, and by studying both their morphometry (e.g., Clark et al., 2009) and internal composition (Stokes et al., 2011), it is possible to gain important new insights to complement those being obtained from direct investigation of modern-day ice sheets.

Former ice sheet flow directions are also crucial to regional drift prospecting, and it has long been recognized that various grain sizes in till can be analyzed to determine their mineralogical and chemical composition to delimit dispersal trains and define source areas of potential resources for mining (McMartin and McClenaghan, 2001). Knowledge of former flow directions is therefore crucial to constrain sampling strategies and procedures. Moreover, once identified, defined paths of glacial transport of distinctive bedrock lithologies have resulted in major new insights regarding the dynamic behavior of paleo-ice sheets (e.g., Dyke and Morris, 1988; Shilts, 1980; Shilts et al., 1979).

This article outlines the principles of glacial inversion techniques for reconstructing former ice sheet flow directions, emphasizing the importance of cross-cutting ice flow indicators, ice sheet basal thermal regime, and paleo-ice streaming.

Glacial Inversion of Paleo-Ice Sheet Beds

Information regarding the presence and extent of paleo-ice sheets has been compiled since the nineteenth century, but it was the advent of aerial photography, satellite remote sensing, and various dating techniques in the latter half of the twentieth century that resulted in robust reconstructions of their maximum extent and subsequent timing of margin retreat (e.g., Denton and Hughes, 1981; Dyke and Prest, 1987a,b; Ehlers and Gibbard, 2004). In contrast, ice sheet reconstructions that incorporate the internal properties of the ice sheet (e.g., the changing flow dynamics, velocity, basal thermal regime, and location of ice divides) have been generated only relatively recently.

Numerical ice sheet models are capable of producing fully three-dimensional simulations of ice sheet dynamics (e.g., Holmlund and Fastook, 1995; Tarasov and Peltier, 2004) but, as noted earlier, such models require validation and evaluation against the glacial geomorphological record. As a result, the last few decades have seen much research effort focused on using the glacial geomorphological record to decipher ice sheet evolution through time, with particular attention to the organization of the subglacial thermal regime, subglacial hydrology, evidence of fast ice flow (paleo-ice streams), and an appreciation of the time-integrated nature of subglacial landscapes (Kleman et al., 2006). This process is known as *glacial inversion* (Kleman and Borgström, 1996) and can be simply defined as “the extraction of ice-sheet properties from glacial geomorphology and geology” (Kleman et al., 2006, p. 192).

Ice sheets leave behind a wealth of evidence for glacial inversion techniques (Kleman and Borgström, 1996). Arguably, the most widespread and commonly utilized in terms of ice flow direction are erosional and depositional landforms. Erosional forms sculpted in bedrock range from small-scale rat tails, striae, and chattermarks to larger forms such as roches moutonnées, whalebacks, and crag-and-tails. Some of these forms may provide only an orientation and not direction (e.g., striae), but where they exhibit a clear longitudinal asymmetry, it is presumed to reflect differential erosion processes at the up-ice (stoss) and down-ice (lee) sides of the form, and ice flow direction is more obvious. For example, steeper stoss slopes on crag-and-tails or irregular plucked surfaces on the lee side of roches moutonnées. It should be noted, however, that while the morphometry of bedrock features can be used to reconstruct ice flow direction and even draw inferences regarding ice velocities (e.g., Roberts and Long, 2005), the characteristics of the underlying geology (e.g., spacing of joints) can introduce additional complexity (cf. Roberts et al., 2010).

Erosional or depositional forms may also be created from unconsolidated sediments, and features aligned parallel to ice flow direction are loosely referred to as glacial lineations. These range from small-scale flutings to larger and more ovoid drumlins and even larger and more elongate mega-scale glacial

lineations. Drumlins are, arguably, the most ubiquitous and, perhaps, the most studied of all glacial landforms, and it follows that they are most commonly employed in reconstructing former ice flow directions.

Traditionally, the 'textbook' description of a drumlin describes a blunter, steeper stoss side and a more gently tapering lee side, and this aerodynamic profile and teardrop planform is widely cited in numerous papers and textbooks. However, it has been recognized that drumlin morphometry varies from this classic description and can range from almost perfectly round to highly elongate spindle forms (e.g., Aario, 1977), with some workers suggesting that the diversity of forms can, in fact, be viewed as a glacier bedform continuum, which might also include transverse features such as ribbed moraine (e.g., Menzies, 1987; Rose, 1987). Recent support for this idea comes from measurements of drumlin morphometry, which reveal a unimodal distribution of various parameters, for example, length, width, and elongation (e.g., Clark et al., 2009). Indeed, the recent availability of high-resolution satellite imagery and digital elevation models has allowed, for the first time, tens of thousands of drumlins to be systematically mapped and measured from a range of settings.

Interestingly, these large data sets have been used to question some long-held assumptions regarding drumlin shape and their utility as evidence of ice sheet flow direction. Spagnolo et al. (2010, 2011), for example, argue that the planform and longitudinal profile of drumlins actually tend toward symmetry, with the major implication being that they are not necessarily a reliable indicator of ice flow direction. With this point in mind, it is important to stress that most studies aimed at reconstructing ice flow direction will utilize a range of available evidence and rarely rely on the characteristics of individual landforms. In this respect, it is the overall pattern and spatial arrangement of a 'swarm' or 'flow-set' of drumlins and their relationship with other landforms that prove most informative (Clark, 1999; Kleman and Borgström, 1996). These might include major terminal moraine systems and/or eskers, which are generally aligned parallel to ice surface slopes and directed toward former margin positions. Thus, it is the appreciation of the entire sediment-landform assemblage (cf. land system: Evans, 2003) that provides the most robust evidence of ice flow direction and indeed ice dynamics, rather than individual landforms. This, along with an evaluation of the age of the landscape, is the essence of the glacial inversion technique, and the following section details recent methodological advances in this important area of paleoglaciology.

Cross-Cutting Ice Flow Indicators, Flow-Sets, Fans, and Ice Streams

Multitemporal Evidence of Ice Flow Direction and Cross-Cutting Landforms

The burgeoning availability of aerial photography and satellite remote sensing products in the latter half of the twentieth century permitted the systematic mapping of ice sheet beds and the production of some pioneering reconstructions of the last midlatitude ice sheets that remain benchmark publications (e.g., Dyke and Prest, 1987a,b). These reconstructions, however, often assumed that the mapped ice flow indicators

(e.g., drumlins) were formed in a radial pattern close to the ice margin and mostly during the decay stages of the ice sheet (e.g., Boulton et al., 1985). The resultant reconstruction of ice flow direction, therefore, often depicted a radial pattern of ice flow from one or more relatively stationary ice domes (Figure 1(a)).

In 1990, Boulton and Clark (1990a,b) questioned the assumption of glacial lineations forming close to the ice margin during deglaciation and instead recognized the ice sheet bed as a 'palimpsest' landscape of flow patterns of different ages that were not all formed in an ice marginal environment. Working on the former North American (Laurentide) Ice Sheet, they grouped coherent patterns of glacial lineations into discrete mapped units which they termed 'flow-sets' (Figure 1(b)). They noted how flow-sets typically cross-cut each other (see Figure 2) and were therefore able to assess their relative age of formation based on principles of superimposition, even in the absence of any absolute dating techniques. The resultant ice sheet reconstruction was more sophisticated than earlier attempts in that it clearly revealed a highly mobile ice sheet with major shifts in the location of ice divides and dispersal centers by 1000–2000 km during the glacial period, many of which have since been confirmed by a more detailed mapping of ice directional indicators (e.g., McMartin and Henderson, 2004).

The discovery of cross-cutting ice flow patterns demonstrated major changes in ice flow direction through time and overturned traditional assumptions regarding the long-term behavior and configuration of ice sheets (Clark, 1993). Later work by Clark (1997) suggested that there were potentially four possible situations that might lead to the creation of cross-cutting flow patterns (see Figure 3): (1) migrating ice divides, (2) the switching on and off of ice streams, (3) ice margin retreat, and (4) flow patterns from more than one glaciation.

Classification of Landform Fans and Flow-Sets

Clearly, the recognition of multitemporal evidence permits more detailed reconstructions of ice dynamics, but the geomorphological record contains additional evidence from which it is possible to glean information about ice dynamics at the time of flow-set formation. In this regard, Kleman and Borgström (1996) highlighted the importance of the basal thermal regime and subglacial hydrology (meltwater features) when deciphering the glaciodynamic context of flow-set formation. In a landmark paper that represented the first attempt at formalizing a methodology for glacial inversion techniques, Kleman and Borgström (1996) classified glacial landscapes or 'fans' (equivalent to flow-sets in Boulton and Clark, 1990a,b) according to (1) their age gradient (were the flow traces/glacial lineations formed synchronously or do they get younger or older down-ice?), (2) the presence or absence of aligned meltwater features, and (3) the basal thermal conditions (frozen or thawed?). They proposed that such considerations result in six fan types (flow-sets) that are known or postulated to exist (Figure 4):

1. *Wet-based deglaciation fans* that consist of flow traces (e.g., glacial lineations) overlain by aligned eskers and preserved as the ice retreats
2. *Dry-bed deglaciation fans* that consist solely of a see-through pattern of meltwater features overprinted on a relict surface

Figure 1 Contrasting approaches to the mapping of evidence of ice flow patterns on the bed of former North Laurentide Ice Sheet. In (a), [Boulton et al. \(1985\)](#) assume that all ice flow indicators (e.g., glacial lineations such as drumlins) are formed close to the ice margin during deglaciation, which results in a radial flow pattern from several large dispersal centers (ice domes). In (b), [Boulton and Clark \(1990a,b\)](#) recognize discrete patches of glacial lineations as separate entities, which they term 'flow-sets,' and which they suggest formed at different times during ice sheet buildup and decay. Relative age dating of these flow-sets using their cross-cutting relationships generates a highly mobile reconstruction of ice flow with major shifts in the location of ice dispersal centers.

- that may contain misaligned flow traces from an older flow stage
3. *Synchronous fans* that consist of abundant flow traces but lack aligned eskers that may represent the sites of former ice streams or slow ice sheet flow well inside the margin
 4. *Surge fans* with a distinctive bottleneck pattern thought to form near-synchronously and with aligned flow traces in the distal part but not in the up-ice part
 5. *Contraction fans* created by inward migration of a preservation borderline other than the ice front (e.g., by refreezing of the bed)

Figure 2 Illustration of the formation of cross-cutting bedform patterns as a result of a switch in ice flow direction. Reproduced from [Clark CD \(1994\)](#) Large-scale ice moulding: A discussion of genesis and glaciological significance. *Sedimentary Geology* 91: 253–268.

6. *Expansion fans* created by outward migration of a preservation borderline other than the ice front (e.g., by refreezing of the bed).

[Kleman and Borgström \(1996\)](#) provided ‘type landscapes’ (cf. type-sites) of fan types 1–4 and outlined the deciphering procedures from defining fan types through to ‘unfolding’ a stack of fans to create a time-slice sequence of ice sheet evolution. An excellent application of these procedures is presented by [Kleman et al. \(1997\)](#), who used the glacial inversion model to reconstruct the evolution of flow pattern in the Fennoscandian Ice Sheet and present time slices from 115 to 9 ka (see [Figure 5](#)). Like [Boulton and Clark \(1990a,b\)](#), their reconstruction identifies several ice sheet configurations with shifts in the location of the main ice divides during buildup and decay. They also note discrepancies between their geomorphologically derived reconstruction and those produced by numerical modeling (e.g., [Holmlund and Fastook, 1995](#)) and highlight the importance of using a

Ice divide migration:

Ice stream activation:

Lobate margin retreat:

Figure 3 Three conceptual models for the cause of cross-cutting ice flow patterns during a single glacial cycle. A further explanation is that some cross-cutting flow patterns might be produced by more than one glaciation. Reproduced from [Clark CD \(1997\)](#) Reconstructing the evolutionary dynamics of former ice sheets using multitemporal evidence, remote sensing and GIS. *Quaternary Science Reviews* 16: 1067–1092.

geomorphologically based reconstruction as a constraint for a numerical model whose output has the added advantage of providing three-dimensional ice sheet evolution and, critically, ice thicknesses.

Preservation of Geomorphology by Cold-Based Ice and Pre-LGM Ice Flow Direction Indicators

A significant aspect of the [Kleman et al. \(1997\)](#) reconstruction was the recognition of fans that record pre-Last Glacial Maximum (LGM) ice flow directions. Indeed, there are several descriptions in the literature of ‘nonglacial’ terrain that appears to have survived ice sheet occupation with minimal alteration and this has been attributed to the sustained presence of cold-based ice (e.g., [Dyke, 1993](#); [Kleman, 1992, 1994](#); [Kleman and Borgström, 1990, 1994](#); [Lagerbäck, 1988](#)), especially where the nunatak hypothesis can be safely rejected through exposure-age dating ([Hättestrand and Stroeven, 2002](#); [Phillips et al., 2006](#)). [Kleman and Glasser \(2007\)](#) provide an overview of the subglacial thermal organization of ice

Figure 4 Six fan types (flow-sets) that are considered relevant for use in glacial inversion models for reconstructing paleo-ice sheets. Reproduced from [Kleman J and Borgström I \(1996\)](#) Reconstruction of paleo-ice sheets: The use of geomorphological data. *Earth Surface Processes and Landforms* 21: 893–909.

sheets and describe how frozen-bed patches span a wide range of spatial scales ([Figure 6](#)). In places, they occur as a mosaic of isolated patches or ‘islands’ in upland landscapes, but it is also clear that, at the ice sheet scale, large frozen-bed areas are controlled by dispersal center locations (ice divides) where there is minimal strain heating.

Significantly, some frozen-bed areas preserve ice directional indicators from earlier stages in the glacial cycle and they can be pieced together to reconstruct the inception and buildup of ice sheets prior to the LGM (e.g., [Kleman et al., 1997, 2010](#)). Clearly, compared to the record of deglaciation post-LGM, ice flow directional indicators and associated flow-sets are much more fragmentary, which inevitably results in a spatially incomplete reconstruction. However, the fragmentary record can be integrated with other available evidence (e.g., till stratigraphy, chronological data) to provide a more speculative interpretation of ice sheet outlines ([Kleman et al., 2010](#)). [Kleman et al. \(2010\)](#) provide such a reconstruction for the Laurentide and Cordilleran Ice Sheets on the basis of glacial inversion principles and utilizing flow-sets that predate the LGM. Although somewhat speculative, it is a testable hypothesis and represents one of the first attempts to systematically synthesize the geomorphological and chronological evidence of ice sheet inception and buildup spanning 115–21 ka. Interestingly, [Kleman et al. \(2010\)](#) compare their reconstruction to

those reproduced in numerical modeling experiments and note key areas of discrepancy. For example, while most models generate a rapid growth toward a mono-domed ice sheet early in the last glacial cycle, the geomorphologically derived reconstruction depicts persistent, dynamically independent dispersal centers in Keewatin and Quebec. Furthermore, [Kleman et al. \(2010\)](#) suggest that the location and size of remnant ice masses at the end of interstadials are likely to be an important control on growth centers during subsequent stadials. They also note variations in the southern extent of the ice sheet margin during early/middle Wisconsin stadials, which are not, generally, reproduced by numerical modeling. Again, this highlights the potential for geomorphologically derived reconstructions to inform and test numerical ice sheet modeling.

Paleo-Ice Streaming

Given the importance of rapidly flowing ice streams to ice sheet mass balance and stability (cf. [Bennett, 2003](#)), any ice sheet reconstruction that omits their activity is likely to be deficient ([Stokes and Clark, 2001](#)). Indeed, the highly dynamic behavior of paleo-ice sheets and the associated changes in ice flow direction that have been described earlier were almost certainly driven by ice stream activity. [Kleman et al. \(2006\)](#),

Figure 5 Fans and relative chronologies defined by ice flow direction indicators relating to the Fennoscandian Ice Sheet. These fans are 'unfolded' to produce a time-slice sequence of ice sheet evolution that spans from 115 to 9 ka. Reproduced from [Kleman J, Hättestrand C, Borgström I, and Stroeven, A \(1997\)](#) Fennoscandian palaeoglaciology reconstructed using a glacial inversion model. *Journal of Glaciology* 43: 283–299.

for example, note that the westward migration of the main ice divide in the Fennoscandian Ice Sheet was probably linked to the onset of four major ice streams in Finland during deglaciation (cf. [Boulton et al., 2001](#); [Kleman et al., 1997](#)). Likewise, it has long been recognized that ice streams are required to produce reconstructions of the Laurentide Ice Sheet ([Figure 7](#))

that comply with geological evidence of low-gradient ice surface profiles (cf. [Fisher et al., 1985](#)). It is, perhaps, surprising therefore that explicit recognition of ice streaming has only been incorporated into glacial inversion methods relatively recently.

Early attempts at reconstructing ice stream location (e.g., [Denton and Hughes, 1981](#); [Dyke and Prest, 1987a,b](#)) were

Figure 6 Frozen-bed patches (gray shading) exist over a range of spatial scales from large areas under former ice divides (a) to isolated 'islands' in upland terrain (d). Note how some frozen-bed patches preserve 'old' glacial lineations (white arrows in (a) and (b) that may be related to pre-LGM ice sheet configurations. (a) northern Fennoscandia; (b) northwestern Canada; (c) low mountains west of Kiruna, northern Sweden; (d) the Cairngorm Mountains, Scotland. Reproduced from Kleman J and Glasser NF (2007) The subglacial thermal organisation (STO) of ice sheets. *Quaternary Science Reviews* 26: 585–597.

augmented with pioneering studies that identified specific geological evidence of their activity, such as distinctive erratic dispersal trains with abrupt lateral margins (Dyke and Morris, 1988; Hicock, 1988) (Figure 8). However, Mathews (1991) noted that there were no diagnostic criteria for distinguishing paleo-ice stream flow-sets and, with this in mind, Stokes and Clark (1999) proposed several specific features that would be expected to characterize a paleo-ice stream 'footprint.' These features were based on a convergence of knowledge gleaned from hypothesized paleo-ice stream locations (e.g., Dyke and Morris, 1988; Hicock, 1988) and the characteristics of contemporary ice streams. These 'geomorphological criteria' include a characteristically large and convergent flow-set, highly attenuated mega-scale glacial lineations with abrupt lateral margins, lateral shear margin moraines, distinctive erratic dispersal trains, and glaciotectionic and/or geotechnical evidence of pervasively deformed till that may accumulate as a till delta or trough mouth fan in marine environments. Thus, although Kleman and Borgström (1996) had speculated that their 'synchronous' and 'surge fans' may be produced by ice streams, the criteria proposed by Stokes and Clark (1999) were explicitly describing a paleo-ice stream land system (Figure 9).

The geomorphological criteria act as an observational template for glacial inversion techniques and numerous paleo-ice streams have been identified in the last decade, such that there is now a fairly comprehensive knowledge of their location from most paleo-ice sheets (Figure 10). Moreover, recent work has revealed abrupt changes in the velocity and trajectory of paleo-ice streams, known as 'flow switching' (e.g., Dowdeswell et al., 2006; Ó Cofaigh et al., 2010; Stokes et al., 2009; Winsborrow et al., 2012), which has also been reported in contemporary ice sheets (Conway et al., 2002) and reproduced in numerical models (Payne and Dongelmans, 1997). These reconstructions provide new insights into the long-term behavior of ice streams (and their potential forcing) and often help to reconcile complex cross-cutting flow patterns. Indeed, ice stream flow-sets are often seen to encroach, superimpose, and even 'behead' other types of flow-sets (cf. Dyke and Morris, 1988; Stokes et al., 2009).

Once identified, the 'known' location of ice streams provides a useful observational record to test numerical models of ice streaming. Given the current attention to improving ice sheet models, there is an urgent need to understand the properties (i.e., boundary conditions) that initiate, sustain, or inhibit ice streaming. This can be achieved through a combined approach that evaluates model predictions of ice streaming against independent geological evidence of their activity. Very few studies have attempted a direct data-model comparison for an entire ice sheet, but Stokes and Tarasov (2010) found generally good agreement for the Laurentide Ice Sheet, although there were some issues in reproducing ice streams that terminated on land that will guide future model development. Evans et al. (2009) also found good agreement between their geomorphologically derived reconstruction of the central sector of the British and Irish Ice Sheet and a simple numerical ice sheet model. Both the geomorphology and the model appear to depict continuous migration of ice dispersal centers, and the model has the additional

Figure 7 Landform swarms of the former Laurentide Ice Sheet thought to be older than the LGM. Despite their fragmentary nature compared to post-LGM records, these flow-sets can be used to reconstruct the evolutionary sequence of the inception and buildup of the ice sheet (see [Figure 8](#)). Reproduced from [Kleman J, Jansson K, De Angelis H, et al. \(2010\)](#) North American Ice Sheet build-up during the last glacial cycle, 115–21 ka. *Quaternary Science Reviews* 29(17–18): 2036–2051.

advantage of providing a guide to the duration of various flow phases, with some modeled flow reversals taking place in <300 years.

[Stokes and Tarasov \(2010\)](#) identified that a major limitation of reconstructions of paleo-ice streams from geomorphological evidence is the lack of dating control on ice stream flow-sets. In this sense, numerical models can provide useful insights into the likelihood of streaming duration at given locations (cf. [Evans et al., 2009](#)), but there is a clear need for additional chronological constraints on ice stream timing to further refine ice sheet reconstructions. This applies equally to non-streaming flow-sets but, if enough radiocarbon dates are available to provide minimum ages on deglaciation, it is possible to date flow-sets and provide an ice sheet reconstruction incorporating ice stream activity up to 250–500-year time steps (see [Figure 11](#); cf. [Stokes et al., 2009](#)).

Ice Flow Indicators Under Contemporary Ice Sheets

One of the most obvious deficiencies of the glacial inversion methods described earlier is that our process understanding of how various landforms are produced is rather limited. This is what [Kleman et al. \(2006\)](#) refer to as the ‘genetic problem,’ that is, deciphering the processes by which, and the conditions under which, particular landforms are created. As [Kleman et al. \(2006\)](#) note, observations of subglacial processes are often

restricted to marginal or thin ice (<100 m) environments or obtained from borehole or geophysical techniques which are limited by their ‘spot’ location and/or poor resolution. Unfortunately, therefore, the landforms that are most important in glacial inversion methods (e.g., glacial lineations and ribbed moraines) are least understood in terms of their genesis. Nevertheless, accumulated knowledge from glacial geomorphological mapping and inversion techniques has contributed some insights into the conditions under which certain landforms are created. For example, the discovery of mega-scale glacial lineations (cf. [Clark, 1993](#)) and their association with paleo-ice stream tracks (cf. [Stokes and Clark, 1999, 2001](#)) has led some to propose that bedform elongation ratio (length:width) is related to ice velocity ([Hart, 1999](#); [Stokes and Clark, 2002](#)), although precisely how a bedform is attenuated is debatable. In contrast, ribbed moraines are rarely associated with fast-flowing ice and are more likely to represent areas of the ice sheet bed associated with oscillations in the basal thermal regime ([Dyke and Morris, 1988](#); [Hättestrand and Kleman, 1999](#); [Kleman and Hättestrand, 1999](#)) and/or possible sticky spots ([Stokes et al., 2008](#)).

Crucially, recent advances in geophysical observations have allowed, for the first time, bedforms to be imaged beneath existing ice sheets at depths of around 2 km below the ice surface ([King et al., 2007, 2009](#); [Smith and Murray, 2009](#); [Smith et al., 2007](#)). Specifically, drumlins appear to be recorded in the onset zone of the Rutford Ice Stream, West Antarctica, where ice velocities accelerate from 72 to >200 m a⁻¹

Figure 8 Reconstructed evolutionary history of the Laurentide Ice Sheet (LIS) based on the flow-sets shown in [Figure 7](#) and with extrapolations based on topographic conditions, glaciological plausibility, and stratigraphical data. Column A gives the preferred age interpretation and column B assigns the Rocksand till to oxygen isotope stage (OIS) 5. LGM, Last Glacial Maximum; LIG, Last Inter-Glaciation. Reproduced from [Kleman J, Jansson K, De Angelis H, et al. \(2010\) North American Ice Sheet build-up during the last glacial cycle, 115–21 ka. *Quaternary Science Reviews* 29\(17–18\): 2036–2051.](#)

([King et al., 2007](#)). Further down the ice stream, where velocities increase to around 375 m a^{-1} , [King et al. \(2009\)](#) report the presence of mega-scale glacial lineations that are indistinguishable from those reported on paleo-ice stream beds ([Figure 12](#)). These observations of the bed confirm the inference from paleoglaciology that bedform elongation is related to ice velocity, but, more importantly, repeat surveys have shown that these bedforms are evolving over very short time-scales, with material being eroded at rates of $\sim 1 \text{ m a}^{-1}$ and

remobilized to form bedforms further downstream, with associated changes in subglacial hydrology ([King et al., 2009; Smith et al., 2007](#)).

Arguably, the most important aspect of these observations is that the formation of bedforms can be linked to specific glaciological conditions (e.g., ice thickness, velocity, and subglacial hydrology), which specifically address the genetic problem. In this sense, observations of the bed of modern-day ice sheets provide the ‘missing link’ between glaciology and

Figure 9 The paleo-ice stream land system of a terrestrially terminating ice stream and the difference between an unaltered imprint (a) and that produced by a retreating ice stream (b) that continually remolds its bed and creates several populations of bedforms (c). paleoglaciology and will considerably refine glacial inversion methods. At the same time, one can assume that future technological advances will permit whole landscapes to be imaged beneath the ice in Greenland and Antarctica, and glacial inversion techniques that have been applied to paleo-ice sheets provide the only observational template to interpret what is likely to be an incredibly complex assemblage of cross-cutting landforms, which will reveal important aspects of the ice sheet's evolutionary history.

Glossary

Ablation: All processes that reduce the glacier mass, including calving.

Ablation zone: The part of the glacier where summer melting exceeds winter accumulation. This includes not only the total melting of the snow cover of the last winter but also a layer of glacier ice. A deficit of mass appears in that area. The zone lies at lower altitudes of the glacier surface. The ablation zone meets the accumulation zone at the equilibrium line.

Accumulation: All processes that increase the glacier mass. Winter snowfalls are the most important source of mass gain. Redepositions of snow by wind and avalanche are important factors on cirque glaciers and on glaciers surrounded by large mountain plateaus and steep valley sides.

Accumulation area ratio (AAR): The ratio of the accumulation zone to the entire glacier with respect to any particular year. The AAR is an indicator of the glacier balance state in the observation year. The ratio is expressed as a proportion of the total area of the glacier.

Accumulation zone: The part of the glacier where snow that has accumulated during the winter does not melt completely in the subsequent summer. An increase of mass is observed in this area. The zone lies normally in the upper part of the glacier. The accumulation zone meets the ablation zone at the equilibrium line.

Annual ablation: The mass loss during 1 measurement year in the fixed date system.

Annual accumulation: The mass gain to the glacier during one measurement year in the fixed date system.

Annual balance: The sum of the annual accumulation (positive) and the annual ablation (negative) at the end of the measurement year (balance year). This term is used in the fixed date system of measuring and reporting of mass balance. Total values are averaged over the entire glacier surface and presented in terms of equivalent water layer (in meters).

Balance year: The time between dates of formation of two consecutive summer surfaces, commonly understood as the time between the beginning of the winter accumulation and the end of the ablation in the subsequent summer (the date of the minimum summer balance). The balance year is rarely exactly equal to one calendar year.

Calving: The process of mass loss with respect to tidewater glaciers (glaciers terminating in the sea or in a lake) and ice shelves (detachment of icebergs).

Climatic equilibrium line: The mean annual equilibrium line over a 30-year period.

Cumulative mass balance: The mass balance summed from particular years of an observation period, which indicates a general trend of the glacier mass to have either grown or shrunk.

Equilibrium line: A line joining points on a glacier surface where winter balance equals summer balance. Normally, this is a line or narrow zone where the summer melting entirely removes the winter snow cover but not any older ice or firn below this. The line separates the accumulation zone from the ablation zone.

Equilibrium-line altitude (ELA): The altitude at which the equilibrium line is noted at the end of any particular balance year. Normally, it is an averaged value with respect to the whole glacier. ELA is used as an indicator of the glacier mass balance state; when it is higher, the net balance is lower and vice versa.

Firn: Old, coarse-grained snow that has survived at least one summer melt season.

Glaciation threshold: The critical level where a glacier can form and is normally calculated by means of the 'summit method' (between the lowest mountain carrying a glacier and the highest mountain without a glacier).

Internal accumulation: The water melted out at times of ablation usually drains from the glacier and its mass is thereby reduced. However, in areas with snow or firn temperatures below zero, meltwater percolating through the summer surface can refreeze and thereby add mass to the lower layers of snow or firn.

Mass balance: The change in mass at any point on a glacier surface at any time (positive or negative mass balance). Normally, it means a change in the mass of the entire glacier in a standard unit of time (the balance year or measurement year).

Mass balance amplitude: The winter balance minus the summer balance (i.e., negative) divided by two.

Mass balance gradients: The rates at which annual ablation and accumulation change with altitude are termed ablation gradient and accumulation gradient, respectively. Together, they define the mass balance gradient.

Mass balance ratio: The ratio between the ablation gradient and the accumulation gradient is termed the balance ratio.

Measurement year: The unit of time used in the fixed date system of mass balance study, which is usually taken at the end of the summer or the beginning of winter and lasts 365 days.

Net balance (b_n): The sum of the winter balance (positive) and the summer balance (negative) through the balance year ($b_n = b_w + b_s$). The term is used in the stratigraphic system of measurement and reporting of mass balance (see Figure 1). Total values are averaged over the entire glacier area and presented in terms of an equivalent of water layer (thickness in meters).

Steady-state equilibrium line: The ELA when the net balance (b_n) is zero.

Summer balance (b_s): The change in mass (commonly negative) during the summer season. It is usually measured

at the end of the summer season and time of formation of the summer surface (minimum balance). The term is often used synonymously with summer ablation.

Summer surface: The glacier surface is formed as a result of the summer balance. This represents the surface of the minimum glacier volume during the balance year.

Temporary equilibrium-line altitude: The equilibrium line at an arbitrarily chosen time of the year. During early spring

the temporary ELA is in the lower glacier area, whereas it is higher up the glacier later in the ablation season.

Winter balance (b_w): The maximum balance value (positive) during the balance year in the stratigraphic system (considered synonymous with winter accumulation).

The time when the maximum balance is measured divides the balance year into the winter and summer seasons.

The rate of growth and retreat of a glacier is mainly controlled by the mass balance, which is the difference between the accumulation and ablation rates. This is termed the net mass balance and commonly measured over a 1-year period. Mass balance is therefore the net gain or loss of ice and snow. Mass balance is highly dependent on the climate conditions. The accumulation includes all materials that add mass to the glacier, such as snow, refrozen slush, hail, rain, and avalanched snow and ice. The ablation includes direct ice melt, iceberg calving, wind erosion/deflation, and sublimation. On most glaciers, accumulation is dominant in the winter months, whereas ablation occurs mainly during the summer. Where an ice sheet or glacier terminates in water, however, iceberg calving may occur throughout the year. Commonly, accumulation exceeds ablation on the upper part of a glacier, whereas ablation is larger than the accumulation in the lower parts. For a 'regular' glacier that is fed by snowfall in its accumulation

area and that loses mass by melting of 'clean' ice in its ablation area, altitudinal mass balance gradients (Figure 1) are approximately linear, with ablation gradients tending to be steeper than accumulation gradients (Furbish and Andrews, 1984; Schytt, 1967). The linear mass balance gradient approach, however, apparently works well in many cases (Kaser, 1995; Kuhn, 1984; Mayo, 1984). In practice, mass balance gradients are influenced by local factors, such as irregularities on the glacier surface (heights and depressions), shading by surrounding topography, and areas of supraglacial debris.

The equilibrium-line altitude (ELA) on modern glaciers is the average elevation where accumulation equals ablation over a 1-year period (Paterson, 1994; Figure 2). Rarely, however, glaciers experience zero net mass balance at the same elevation across the entire width of the glacier due to local topographic and climatic variations in accumulation and ablation. Thus, the ELA is the average altitude of the equilibrium line. The

Figure 1 Net balance gradients of Nigardsbreen, an outlet glacier from Jostedalbreen in western Norway, in two balance years with contrasting net mass balance situations (1987–88 and 1988–89). The steady-state ELA and the 1962–2004 ELA are indicated. Data provided by NVE (Oslo, Norway).

'steady-state ELA' is defined as the ELA when the annual net balance is zero, and it can be calculated by linear regression analysis of annual net balance data and corresponding ELAs over some years (Figure 3). When the annual ELA coincides with the steady-state ELA, which rarely occurs, the mass of ice is in equilibrium with the climate. The steady-state ELA is therefore merely a theoretical term. The concept, however, is very useful because it provides a measure of the climatic means related to certain glacier positions and geometries. The 'climatic ELA' is the average ELA over a 30-year period (corresponding to a climate 'normal' – 30-year mean – period).

Climate processes influencing the ELA on glaciers involve ablation (mainly controlled by summer temperature, T) and

Figure 2 The ELA on the glacier Austdalsbreen, an eastern outlet glacier from Jostedalbreen in western Norway. Photograph by A. Nesje.

direct snowfall (precipitation, P), giving the TP-ELA. In addition, wind (W) transport of dry snow is an important factor for the glacier mass balance, particularly during the accumulation season. On plateau glaciers, snow deflation and drifting dominate on the windward side, whereas snow accumulates on the leeward side. By calculating the mean ELA in all glacier quadrants on a plateau glacier, the influence of wind on plateau glaciers may be negligible. The resulting ELA is therefore defined as the temperature–precipitation ELA (TP-ELA). The TP-ELA reflects the combined influence of the accumulation season precipitation and ablation season temperature (Dahl and Nesje, 1992). On wind-exposed mountain plateaus, the snow may deflate and accumulate in lower cirques and valleys, either by direct accumulation on the cirque/valley glaciers or by avalanching from the mountain slopes. The accumulation on the cirque/valley glaciers may therefore be significantly higher than the local precipitation indicates (Dahl and Nesje, 1992). The mean ELA on a plateau glacier therefore defines the TP-ELA, whereas the ELA on a cirque glacier, commonly influenced by wind-transported snow, gives the TPW-ELA. Therefore, the TPW-ELA is commonly lower than the TP-ELA (Figure 4). Leeward accumulation of windblown snow, including avalanching from the cirque walls, is an important factor influencing the mass balance of cirque glaciers. Due to the potential upslope transport of dry snow by wind, the additional accumulation of snow in a cirque is commonly difficult to estimate. Dahl et al. (1997) therefore introduced a ratio between the catchment area above the TPW-ELA (D) and the reconstructed glacier accumulation area (A) as a rough measure of the potential for additional snow by wind transport and avalanching in cirques. A low D/A ratio indicates a TPW-ELA close to the TP-ELA with only minor additional supply of windblown snow that is typical for cirque glaciers surrounded by steep alpine peaks. A high D/A ratio, on the other hand,

Figure 3 The steady-state ELA (=1560 m; ELA where the net balance is zero) at Nigardsbreen, an eastern outlet glacier from Jostedalbreen, western Norway. Based on data (observation period 1962–2004) provided by the Norwegian Water Resources and Electricity Directorate.

Figure 4 Schematic examples showing the difference between the temperature–precipitation equilibrium-line altitude (TP-ELA) at plateau glaciers and the temperature–precipitation–wind equilibrium-line altitude (TPW-ELA) at cirque glaciers. Modified from Dahl SO and Nesje A (1992) Palaeoclimatic implications based on equilibrium-line altitude depressions of reconstructed Younger Dryas and Holocene cirque glaciers in inner Nordfjord, western Norway. *Palaeogeography, Palaeoclimatology, Palaeoecology* 94: 87–97, with permission.

shows the potential for large amounts of windblown snow onto a cirque glacier and a TPW-ELA well below the TP-ELA. This is typical for a cirque glacier surrounded by a large mountain plateau.

Three equations derived from a close exponential glacier–climate relationship at the ELA of Norwegian glaciers were implemented in a geographical information system (Lie et al., 2003). The equations enable calculation of (1) the minimum altitude of areas climatically suited for present glacier formation, (2) quantification of the glacial build-up sensitivity (GBS) in an area, and (3) calculation of the theoretical climatic TP-ELA (based on temperature and precipitation data from meteorological stations in southern Norway) in presently nonglaciated areas by combining GBS with terrain altitude. The approach is primarily intended for reconstruction of paleo-ELAs in areas with no present glaciers.

There is a very close connection between the ELA and local climate, particularly winter accumulation (snowfall), summer temperature, and wind strength causing snow transport during the accumulation season. The ELA is therefore sensitive to perturbations of these variables; high winter snowfall combined with low summer temperatures the following summer gives a low ELA, whereas low winter accumulation followed by a warm summer yields a high ELA. Fluctuations in the ELA over time (Figure 5) are therefore an important indicator of climate change and commonly allow reconstructions of past climates. Thus, paleoclimatic reconstructions based on former glacier extent commonly make use of reconstructed ELAs. Data on past variations of ELAs therefore provide an important source of proxy paleoclimatic data in glaciated regions throughout the world.

Relationships Between Precipitation–Temperature and the ELA

Relationships between temperature and precipitation at ELAs on glaciers have been established by statistical/analytical approaches (Liestøl in Dahl et al., 1997; Nesje and Dahl, 2000; Ohmura et al., 1992; Shi et al., 1992; Sissons, 1979; see Figure 5). The positive correlation between these two variables for a wide range of glaciers reflects the fact that higher values of mass turnover at the ELA require higher ablation (higher summer temperatures) to balance the annual specific mass budget. The curves in Figure 4 yield fairly similar values and a curve shape in the temperature range of -2 to 4°C and accumulation–precipitation up to 3500 mm. The approaches of Ohmura et al. (1992) and Nesje and Dahl (2000), however, deviate significantly for temperature and precipitation $>4^{\circ}\text{C}$ and >3500 mm, respectively. Some of the discrepancy may be explained by the fact that Ohmura et al. use winter accumulation plus summer precipitation at the ELAs, whereas Nesje and Dahl use only winter (1 October–30 April) precipitation. (For details on the different approaches, see Figure 5.)

The temperature–precipitation relationship also explains the regional rise in glacier ELAs with increasing distance from moisture sources. In areas of lower precipitation, the temperature required to melt the annual accumulation at the ELA does not need to be as high as in areas of high precipitation. Consequently, ELAs tend to be at higher elevations in areas with low ablation season temperatures than in areas with higher ablation season temperatures. If paleo-ELAs have been reconstructed and if paleotemperatures are reconstructed from independent proxies (pollen, faunal remains, etc.) nearby, former

Figure 5 Temperature–precipitation relationships at glacier ELAs. Liestøl in Sissons (1979): mean summer (1 May–30 September) temperatures and winter (1 October–30 April) accumulation at the ELA of ten Norwegian glaciers (Ålfotbreen, Engabreen, Folgefonna, Nigardsbreen, Tunsbergdalsbreen, Hardangerjøkulen, Storbreen, Austre Memurubreen, Hellstugubreen, and Gråsubreen). Ohmura et al. (1992): mean summer temperature in free atmosphere at ELA and annual total (winter accumulation plus summer precipitation) at ELA for 70 mid- and high-latitude glaciers. Shi et al. (1992): mean summer temperature and annual precipitation at the ELA of 17 high Asian glaciers. Nesje and Dahl (2000): winter (1 October–30 April) precipitation and summer (1 May–30 September) temperature at the ELA in corresponding balance years calculated from adjacent meteorological stations. The ELAs at the four glaciers used were Ålfotbreen, Hardangerjøkulen, Hellstugubreen (all three in southern Norway), and Brøggerbreen (Svalbard), together with summer temperature data from adjacent meteorological stations Sandane, Finse, Øvre Tessa, and Isfjord Radio, respectively.

winter or total precipitation at the ELA can be calculated from temperature–precipitation relationships (Dahl and Nesje, 1996). Regional variations of glacier ELAs can be used to infer former precipitation gradients that may allow prevailing moisture sources and circulation patterns to be reconstructed (Lehmkuhl, 1998; Lehmkuhl et al., 1998; Miller et al., 1975). In addition, reconstructed ELAs of former glaciers have been used to correlate moraines in mountain regions (Maisch, 1982). However, the term ELA has been applied to several altitudinal indices calculated for past glaciers. The relationship between some of these indices and climate, however, has not been firmly established. Paleoclimatic reconstructions based on these indices may therefore be inaccurate (Benn and Lehmkuhl, 2000). In some high mountain regions, the relationship between climate and glacier ELAs may be complicated by avalanches and debris cover on the glacier surface.

Approaches to Calculating Paleo-ELAs

The determination of steady-state ELAs on modern glaciers should be based on measurements of glacier mass balance

over several consecutive years (Figure 6). If we want to calculate the ELAs when a glacier was larger than at present or if the glacier has melted completely, other methods have to be used. Several approaches for calculating/estimating the ELAs of former glaciers from geomorphological evidence have been developed (Gross et al., 1976; Meierding, 1982; Torsnes et al., 1993; see review by Benn and Lehmkuhl, 2000). The most common approaches for reconstructing paleo-ELAs are the use of the following:

- The maximum elevation of lateral moraines (MELM)
- The median elevation of glaciers (MEG)
- The toe-to-headwall altitude ratio (THAR)
- The toe-to-summit altitude method (TSAM)
- The accumulation area ratio (AAR) to the total glacier area
- The balance ratio (BR) method
- Cirque floor altitudes
- Proglacial sites

The concepts of the different methods vary significantly, as do their reliability and ease of use. Some approaches are based on detailed evaluation of mass balance and glacier hypsometry (distribution of glacier area over its altitudinal range). Others are based on the large-scale morphology of the glacier catchment, the altitude of marginal moraines, and the cirque floor. A literature survey indicates that ELA depressions from modern values during the Last Glacial Maximum, Younger Dryas, and the ‘Little Ice Age’ were typically in the range of 1000 ± 300 , 500 ± 200 , and 100 ± 50 m, respectively.

Maximum Elevation of Lateral Moraines

Due to the nature of glacier flow toward the center above the ELA and toward the margin of the glacier below the ELA, lateral moraines are theoretically deposited only in the ablation zone below the ELA. As a result, the MELM should ideally reflect the corresponding ELA (Figure 7). This method is considered best suited for long valley glaciers with large, continuous lateral moraines. However, there are several problems with this approach. First, englacial material may not reach the glacier surface immediately below the equilibrium line. Thus, lateral moraines may not form at the actual ELA, but below it. Second, it is difficult to assess whether or not a lateral moraine is preserved entirely in the upper part due to degradation on steep slopes. Consequently, ELA estimates derived from eroded/degraded lateral moraines may be too low. Third, the valley sides may be too steep for deposition of lateral moraines, giving estimates of the former ELA that are too low. Finally, if initial glacier retreat is slow, additional moraine material could be deposited in the prolongation of the former steady-state lateral moraine. A continuous supply of debris from the valley or cirque walls during glacier retreat may lead to estimates of the former ELA that are too high. Despite its problems, the MELM approach is considered the most reliable method in cases in which former glaciers were covered by debris and the mass balance gradient is poorly or not known. Special consideration must be paid to the topographic setting and the preservation of moraines. The MELM approach does not need detailed topographic maps for the entire glacier area. The altitude of the moraines can easily be determined photogrammetrically or by an altimeter in the field.

Figure 6 Observed ELAs on Hellstugubreen (Jotunheimen in central southern Norway) and Nigardsbreen (Jostedalbreen in western Norway) from the early 1960s to 2004. Data from NVE (Oslo, Norway).

Median Elevation of Glaciers

This approach places the ELA halfway between the glacier front and the top of the glacier. Empirical evidence from modern glaciers, however, suggests that the MEG overestimates the ELA. In addition, this method fails to take into account variations in valley morphology, which strongly affects the area/elevation distribution of a glacier. However, it works reasonably well for small glaciers with an even area/altitude distribution. The main problem is commonly to define the headward limit of a former glacier.

Toe-to-Headwall Altitude Ratio

This method assumes that the ELA lies at a fixed proportion of the vertical distance between the highest and lowest part of a former glacier. A ratio between the maximum and minimum altitude of a glacier (THAR) has been used as a quick estimate to calculate the ELA. Ratios of 0.35–0.4 were used by Meierding (1982) for glaciers in Colorado. Values of 0.4–0.5 were used by Porter et al. (1983) for ‘clean’ ice glaciers. Debris-covered glaciers in California, however, have rather high THARs of 0.6–0.8 (Clark et al., 1994). A THAR of 0.60 ± 0.12 has been obtained from 15 Norwegian glaciers with modern mass balance measurements and ELA observations (A. Nesje, unpublished data). The THAR approach is considered a rough way of estimating former ELAs because it does not take into account glacier hypsometry and mass balance. In addition, a major problem is to define the headward limit of a former glacier. The THAR approach allows rapid estimates of former ELAs in remote areas with poor or inaccurate maps.

Toe-to-Summit Altitude Method

A way to overcome the problem of defining the upper limit of a former glacier is to use the maximum altitude of the glacier catchment. Louis (1955) suggested that the ELA may be calculated from the arithmetical mean of the altitude of the highest mountain and the terminal moraine. For the European Alps, Gross et al. (1976) demonstrated that this approach yields ELAs that are approximately 100 m too high. For modern glaciers in the northernmost mountain range of the Mongolian Altai, the inferred values are in agreement with snowlines on glaciers observed in the field and on aerial photographs (Lehmkuhl, 1998). The TSAM approach may cause inaccurate ELA estimates where the highest mountain peak is not representative of the catchment as a whole and does not contribute significantly to glacier accumulation. Despite its crudeness, the TSAM method gives rapid estimates of former ELAs in remote areas. ELA estimates based on the TSAM method should be determined for each region separately because there may be significant variations due to variations in glacier type.

AAR to the Total Glacier Area

The ratio of the accumulation area to the total area (AAR) is based on the assumption that the steady-state AAR of former glaciers is typically 0.55–0.65 (Porter, 1975). An AAR of 0.6 ± 0.05 is generally considered to characterize steady-state conditions of valley/cirque glaciers. Ice caps and piedmont glaciers, however, may differ significantly from this ratio. Gross et al. (1976) inferred a mean AAR value of 0.67 for glaciers in the European Alps. The AAR of a glacier varies mainly as a function of its mass balance; ratios less than 0.5 indicate

Figure 7 The principle of calculating the depression of the ELA on a cirque glacier based on the maximum elevation of lateral moraines. Dashed lines on the top panel indicate surface contours, and arrows on both panels indicate ice flow direction.

negative mass balance, ratios of 0.5–0.8 correspond to steady-state conditions, and values higher than 0.8 reflect positive mass balance regimes. For modern mid- and high-latitude glaciers, steady-state AARs typically lie in the range 0.5–0.8.

The AAR approach requires contour maps of former glacier surfaces, and therefore, this method can be used only where detailed topographic data/maps are available. Information about mass balance gradients is not required for the AAR method. AARs are commonly determined empirically and should be based on observations of modern glaciers in the region of interest (Gross et al., 1976). Debris-covered glacier tongues have lower AARs than clean glaciers. Thick debris

(>2 cm) lowers the ablation and increases the size of the ablation area required to balance accumulation (Clark et al., 1994). In high mountain regions, AARs commonly vary according to the extent and distribution of debris cover in the ablation area. There is a need to determine the range of AARs associated with different glacier geometries and mass balance characteristics (Benn and Lehmkuhl, 2000).

The largest source of inaccuracy related to the AAR method of determining the ELA on former glaciers is the reconstruction of the surface contours, especially if the glacier margins intersect valley-side topographic contours at small angles or coincide with them for some distance. However, this source of error

is considered to be randomly distributed and is not considered to introduce major deviations from representative conditions. In addition, this method only requires glacier reconstruction as high as the former ELA. A theoretical evaluation of the AAR approach, using changing slope angles and valley morphology on idealized glaciers, shows that glaciers advancing into flat areas underestimate the ELA depression, whereas glaciers moving into areas of increasing slope angle overestimate the climatic ELA difference. Consequently, topographical and morphological effects on calculated ELA depressions on glaciers must be carefully evaluated.

BR Method

The BR method is a refinement of the AAR approach. As discussed previously, one shortcoming of the AAR method and also the MEG approach is that they do not fully account for variations in the hypsometry. To overcome this problem, a BR method was developed by [Furbish and Andrews \(1984\)](#). This approach takes account of both glacier hypsometry and the shape of the mass balance curve and is based on the fact that for glaciers in equilibrium, the total annual accumulation above the ELA must balance the total annual ablation below the ELA. This can be expressed as the areas above and below the ELA multiplied by the average accumulation and ablation, respectively. The BR approach assumes that the accumulation and ablation gradients are approximately linear, that the ratio between the two is known, and that the hypsometry of the glacier is known. The BR method can thus only be used where detailed topographic maps are available and the surface contours of former glaciers can be reconstructed in detail ([Benn and Gemmel, 1997](#)). Because accumulation and ablation gradients are controlled by different climatic variables, the accumulation and ablation gradients generally have different values, with the ablation gradient somewhat steeper than the accumulation gradient. In a study of 22 glaciers in Alaska, [Furbish and Andrews \(1984\)](#) found that BRs clustered around 1.8, meaning that the ablation gradient is 1.8 times greater than the accumulation gradient. BRs are different under different climate conditions; they are lowest in polar areas and highest in tropical regions.

The BR approach is best suited to snow-fed, clean glaciers in areas with detailed maps. However, the method is not appropriate where a significant part of the accumulation is by avalanching from surrounding mountains and/or where debris cover strongly influences the ablation gradient. [Benn and Gemmel \(1997\)](#) published a spreadsheet program that rapidly calculates glacier ELAs using the BR method, which allows hypsometric variations to be accounted for in ELA reconstructions.

Cirque Floor Altitudes

Cirque floor levels or altitudes have been used as indicators of the elevation of former glacier snowlines for Pleistocene glaciers. However, the elevation of the cirque floor/basin does not have a close relationship with the ELA of the glacier that formed it ([Benn and Lehmkuhl, 2000](#)). Cirques develop cumulatively over many glacial cycles and therefore cannot be attributed to any particular glacial event. However, they may give some insight into regional trends in glaciation levels and average climatic conditions over longer timescales.

Proglacial Sites

Several approaches have been applied to record past variations in ELAs based on lacustrine and terrestrial proglacial sites. [Dahl et al. \(2003\)](#) presented a conceptual model of glacier meltwater-induced sedimentation in which a variety of proxies are related to the occurrence and size variations (as a response to variations in the ELA) of a glacier in a catchment.

Validity of Different Approaches for Paleo-ELA Reconstruction

The mass balance characteristics of glaciers in high mountain environments complicate the relationship between glacier ELAs and climatic variables such as precipitation and air temperature. Therefore, methods of ELA reconstruction employed in low-relief environments are commonly not applicable in high mountains or require some modification ([Benn and Lehmkuhl, 2000](#)). [Leonard and Fountain \(2003\)](#) examined the validity of two methods for estimating glacier ELAs from topographic maps. The ELA determined by the inflection of the contour lines on the glacier (kinematic ELA) and the mean elevation of the glacier correlates well with the ELA determined from mass balance data (measured). The data were normalized and a fairly high correlation ($r^2 = 0.59$) was obtained between observed and kinematic ELAs. The mean of the normalized kinematic ELAs was consistently located down-glacier from the observed ELA, in agreement with theory. The normalized mean elevation of the glacier yielded no correlation and suggests that the THAR approach is not a good approximation for the ELA. Kinematic waves had apparently no effect on the position of the kinematic ELA. Topographic maps of glacier surfaces can therefore be used to infer the position of the ELA and provide a method for estimating paleo-ELAs from historic topographic maps and reconstructed paleoglaciers.

Small glaciers have short response times to climate change and they are therefore well suited for climate monitoring. Glacier responses to climate, or their mass change, may be suggested by a change in the ELA. However, several regional climatic reconstructions have neglected the importance of local variations in ELAs in preference for regional trends ([Carrivick and Brewer, 2004](#)). Ignoring the importance of local topographic components in mass balance estimates for small glaciers close to the glaciation threshold/level may lead to erroneous climatic reconstructions. Of 510 small valley and cirque glaciers digitized across northern Scandinavia, 284 were considered suitable for inferring an ELA ([Carrivick and Brewer, 2004](#)). The inferred ELA was derived from the median elevation and several local topographic variables using regression analysis. The glacier elevation, area, slope, and aspect parameters were found to be the best predictors of the local ELA. ELA estimations improved from 77% up to 94% accuracy when topographic parameters for every grid cell within rasters representing glacier surfaces were computed rather than using subjective measurements from topographic maps. Regional ELA trend surfaces, interpolated between the local ELA values, differed in representing the local variability, depending on the distribution and accuracy of the local ELA values. A second-order polynomial trend surface represented ELA variations most accurately across the study area, within the local

measurement accuracy of ± 100 m. Carrivick and Brewer (2004) concluded that current subjective topographic map-based analyses are unlikely to be sufficiently accurate for predicting the regional ELA of small, sensitive, and marginal glaciers, unless GIS-based spatial analyses are made at a reasonable resolution.

Conclusion

The ELA, which marks the area or zone on a glacier where accumulation is balanced by ablation over a 1-year period, is sensitive to variations in winter precipitation, summer temperature, and wind transport of dry snow. When the annual net mass balance is negative, the ELA rises, and when the annual mass balance is positive, the ELA declines.

Fluctuations in the ELA are important indicators of climate change. This may allow reconstructions of accumulation season precipitation, ablation season temperature, and prevailing snow-bearing wind directions. Paleoclimatic reconstructions based on former glacier extent commonly include estimates of ELAs and depression of ELAs from present values. Several methods have been developed to estimate steady-state ELAs of former glaciers in high mountainous regions. The BR method is the only approach that is directly linked to glacier mass balance. The AAR method is related to generalized mass balance relationships. The MELM builds on the relationship between glacier mass balance and the distribution of glaciogenic deposition, whereas the THAR, TSAM, and cirque floor altitudes are related to the large-scale morphology of the glaciated catchments and therefore not directly linked to glacier mass balance. The BR approach is most useful on snowfall-fed, clean glaciers where mass balance gradients were approximately linear. The AAR method can be applied to clean, snowfall-fed glaciers when appropriate values of the steady-state AAR are taken into account. The MELM approach is a quick method of estimating former ELAs in remote, high mountain regions. This method does not require detailed topographic maps. The THAR and cirque floor altitudes are considered as crude estimates of paleo-ELAs. The TSAM method may provide a useful and rapid method in areas where mass balance data are not available. Researchers who study former glaciers should provide detailed descriptions of their information on the method (s) (multiple methods should be used) used to calculate former ELAs. A literature survey indicates that ELA depressions (from modern elevations) during the Late Glacial maximum, Younger Dryas, and the Little Ice Age were typically in the range of 1000 ± 300 , 500 ± 200 , and 100 ± 50 m, respectively.

Trimlines and Paleonunataks

C K Ballantyne, University of St. Andrews, St. Andrews, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

Nunataks are mountain summits surrounded on all sides by glacier ice (Figure 1), and summits formerly surrounded by ice during Quaternary glacial maxima are referred to as paleonunataks. A periglacial trimline (sometimes termed a glacial trimline) represents the upper level to which glacial erosion has removed or 'trimmed' a pre-existing cover of regolith (weathered rock debris) on the flanks of nunataks or other mountain slopes. In many areas, periglacial trimlines have been preserved since late Pleistocene deglaciation. In some circumstances, such trimlines can be employed to delimit the configuration and maximum altitude reached locally by glacier ice during the Last Glacial Maximum (LGM) of ~26–~21 ka BP (Figures 2 and 3), or later readvances of more restricted extent. Not all periglacial trimlines, however, represent the former upper limit of glacier ice. In many areas, the contrast between glacially eroded terrain on low ground and apparently intact tors and regolith cover on plateaus reflects preservation of the latter under cold-based ice within a former ice sheet. Where this is the case, trimlines have important implications for the subglacial thermal regime of former ice cover, but provide only a minimum estimate of former ice-surface altitude. Periglacial trimlines are unrelated to vegetation trimlines. The latter are phytological boundaries marking the extent of recent (Little Ice Age) glacier advances or readvances, and their use in glacier reconstruction is limited to establishing the extent of ice advances within the past millennium.

Periglacial trimlines and their potential for reconstructing the dimensions of former ice sheets were recognized by James Geikie as early as 1873, and for over a century, geomorphological evidence for trimlines has been employed in mountain areas to estimate the maximum vertical dimensions and/or surface configuration of late Pleistocene ice sheets or Late Glacial readvances, particularly in Norway, Scotland, Labrador, and Arctic Canada (Ballantyne et al., 1998; Ives, 1978; Nesje et al., 1988). Over the past three decades, however, an accumulating body of evidence has demonstrated that many trimlines originally interpreted as being of ice-marginal origin actually reflect altitudinal zonation of erosion within former ice sheets that completely buried the summits of presumed paleonunataks, necessitating radical reinterpretation of ice thickness and ice-surface configuration at the LGM (e.g., André, 2004; Ballantyne, 2010a; Ballantyne and Hall, 2008; Briner et al., 2003; Fabel et al., 2002; Fjellanger et al., 2006; Kleman and Glasser, 2007; Marquette et al., 2004; Staiger et al., 2005). Appreciation that trimlines are interpretable in more than one way has led to the development of increasingly sophisticated approaches to date and validate trimlines, and to aid correct interpretation of trimline evidence.

Hypotheses of Trimline Formation

A periglacial trimline represents a weathering limit that separates an upper zone of more advanced rock breakdown from a lower zone characterized by glacially smoothed rock surfaces

that exhibit limited post-deglaciation rock weathering. In glaciated mountains, an upslope change (sharp or transitional) from glacially smoothed bedrock to terrain characterized by angular, often shattered bedrock outcrops and extensive regolith cover is common (Figures 2 and 3). The boundary between the two may potentially be interpreted in five ways (Figure 4).

1. The ice-marginal (nunatak) hypothesis: the weathering limit represents the upper limit of a warm-based (erosive) ice sheet at the LGM, with ice-free nunataks remaining above the ice (Figure 4(a)).
2. The ice-cap hypothesis: the weathering limit represents a thermal boundary between a warm-based (erosive) ice sheet at the LGM and thin, nonerosive cold-based ice caps occupying some or all of the higher ground (Figure 4(b)). This hypothesis represents a transitional case between (Figures 4(a) and 4(c)).
3. The englacial trimline hypothesis: the weathering limit represents a former englacial transition from erosive, warm-based ice occupying surrounding valleys to passive, cold-based ice on summits and plateaus (Figure 4(c)). This hypothesis implies that at the LGM, the highest summits were overridden by the regional ice sheet.
4. The readvance hypothesis: the weathering limit represents the upper limit of warm-based (erosive) ice during a post-LGM readvance (Figure 4(d)).
5. The climatic hypothesis: the weathering limit represents the lower boundary of widespread breakup of rock under periglacial conditions since deglaciation, and is thus unrelated to former ice-sheet or valley-glacier dimensions (Figure 4(e)).

Under hypotheses 1–4, the weathering limit represents the upper limit of glacial erosion and thus may be defined as a periglacial trimline. Cases 1 and 2 imply that the trimline marks the upper limit of regional ice cover at the LGM and thus may be employed to constrain the dimensions of LGM ice cover. Case 4 implies that the trimline represents the upper surface of a later readvance. Case 3 implies that the last and possibly earlier ice sheets were sufficiently thick to cover all high ground, but failed to erode older regolith covers on summits and plateaus. In case 5, the weathering limit is unrelated to glacial erosion and cannot be described as a trimline.

The age of blockfields and other regolith covers on high ground is critical for differentiating hypotheses 1–3 from 4 and 5. Most regolith covers on midlatitude or subarctic mountains are essentially relict features that predate the LGM. In some instances, these may even exhibit features possibly inherited from Neogene saprolite (e.g., André, 2004; Marquette et al., 2004; Paasche et al. 2006), though the characteristics of many blockfields appear consistent with development under Pleistocene periglacial conditions through exploitation of stress-release joints by frost wedging (Ballantyne, 1998, 2010b; Goodfellow et al., 2009). On some well-jointed or fissile lithologies, however, incipient blockfields and other forms of mountain-top regolith

Figure 2 Trimline representing the extent of glacier ice at the Last Glacial Maximum (LGM) (Otira Glaciation), Lake Wakatipu, South Island, New Zealand. Below the trimline, the bedrock is strongly ice-molded; above the trimline are outcrops of shattered bedrock and an extensive regolith cover. The trimline descends in altitude from right to left, away from the ice-shed location in the Southern Alps.

cover have developed locally since downwastage of the last ice sheet. In such cases, the lower limit of *in situ* weathered regolith bears no relation to former ice-sheet maxima, though it may represent a trimline cut by a post-LGM readvance. In the western Highlands of Scotland, for example, it is possible at some locations to identify two trimlines: an upper and older trimline representing the approximate maximum altitude of effective glacial erosion at the LGM and a lower and younger trimline that represents the upper limit of glaciation during the Younger Dryas Chron of ~12.9–11.7 ka BP. These two trimlines separate an uppermost (periglacial) weathering zone of advanced rock breakdown from an intermediate (Late Glacial) weathering zone of more limited bedrock disruption and a lowermost weathering zone of ice-molded bedrock exhibiting only superficial weathering (Ballantyne, 1998; Figure 5). The lower trimline has been employed by several authors to delimit the maximum ice-surface altitude and configuration during the Younger Dryas chronozone (e.g., Thorp, 1981, 1986). The clarity of the younger trimline, however, is strongly conditioned by lithology: well-jointed rocks (notably quartzite) have broken down to form incipient blockfields in the interval between ice-sheet downwastage and the Younger Dryas glacier readvance, whereas more massive lithologies such as gneiss have remained essentially intact since ice-sheet downwastage. Present-day blockfield development appears to be limited to permafrost environments that experience severe annual freezing (Ballantyne 2010b).

Figure 3 Granite paleonunatak in Yosemite National Park, California. A clear trimline separates a summit blockfield from ice-molded rock on lower slopes and marks the maximum altitude of glacier ice during the LGM (Tioga Glaciation).

Trimline Geomorphology

The identification of periglacial trimlines is based on the contrast between lower slopes exhibiting evidence of glacial erosion and deposition, and higher areas characterized by regolith cover and unmodified assemblages of periglacial features (Figures 2, 3, 6, and 7). Among the most useful forms of glacial

Figure 4 Hypothesis of trimline formation: (a) the ice-marginal (nunatak) hypothesis, (b) the ice-cap hypothesis, (c) the englacial trimline hypothesis, (d) the readvance hypothesis, and (e) the climatic hypothesis. For explanation, see text.

evidence are ice-molded or ice-abraded bedrock forms (roches moutonnées, whalebacks, glacially smoothed bedrock slabs, gouges, striae, and chattermarks) and erratics and other glacially transported perched boulders that rest on bedrock

slabs or on frost-weathered debris (Figure 8). Unmodified periglacial terrain on mountains is characterized by the absence of glacial evidence and by the presence of frost-shattered tors and bedrock outcrops, a thick cover of blockfield (felsenmeer), scree, or other weathered regolith, and a range of relict frost-action landforms that have developed on the regolith cover, such as solifluction sheets, solifluction lobes, and relict patterned ground. Because identification of trimlines is based on contrasts in terrain characteristics, they tend to be clearest in areas where the flow of glaciers or ice streams was topographically constrained and thus accelerated. Some of the clearest trimlines are therefore those cut across bedrock on truncated spurs. Conversely, trimlines are much less evident near former ice sheds (the highest points of former ice sheets) where ice sliding velocities were low. For similar reasons, clear trimlines tend to be better developed in maritime areas formerly occupied by fast-moving, erosive ice than in more arid continental areas where the mass budget of former ice masses was lower and ice movement slower.

Four problems affect the identification and mapping of periglacial trimlines. First, there has often been downslope movement of regolith since deglaciation, so that trimlines are obscured on moderate or steep slopes. This problem may be overcome by mapping the geomorphological evidence on low-gradient areas unaffected by mass movement (cols, shoulders, and summit plateaus) to constrain the former upper limit of glacial erosion and lower extent of unmodified periglacial terrain. Second, as noted previously, some lithologies have experienced disruption by frost action since glacial downwastage, and on such lithologies, incipient blockfields or other types of frost-weathered regolith may have developed below the upper limit of glacial erosion at the LGM (Ballantyne, 1998). In such cases, establishment of the former upper limit of glacial activity must rely on the distribution of erratics, perched boulders, or glacially detached blocks rather than glacial erosional landforms (Sellier, 1995). Third, some mountain landscapes take the form of gently rolling plateaus or plateau remnants that terminate abruptly at the edges of deep glacial troughs, notably in Norway, Sweden, Svalbard, Greenland, Scotland, Québec-Labrador, Arctic Canada, parts of Antarctica, and the Laramide Ranges of the western United States. In such areas, trimlines are usually absent because the troughs are flanked by steep cliffs, though the lowermost limit of blockfields may provide a constraint on the former altitudinal limit of glacier ice provided that there is no evidence for former ice cover on the plateau. In many areas, however, investigation of plateau surfaces has revealed evidence of former glacier ice cover in the form of occasional erratics (Figure 8), glacially transported perched boulders, glacially detached blocks, ablation moraines, or meltwater channels (e.g., Fjellanger et al., 2006; Landvik et al., 2003; Marquette et al., 2004; Sellier, 1995), even though evidence for glacial erosion of plateau surfaces may be absent, very localized, or limited to modification of tors (e.g., André, 2004; Hall and Glasser, 2003; Hall and Phillips, 2006). Such features provide compelling evidence for blockfield survival (though not necessarily at the LGM) under a cover of cold-based glacier ice (hypotheses 2 and 3). Finally, even where a clear weathering limit is identified, its

Figure 5 Formation of two trimlines separating three weathering zones. (1) Prolonged weathering results in an extensive regolith mantle. (2) This debris is trimmed by an ice sheet at the LGM. (3) During and after ice-sheet downwastage, weathering attacks bedrock below the trimline. (4) A later ice advance or readvance trims the lower weathering zone. (5) Glacier retreat leaves a zone of relatively unweathered ice-scoured bedrock and glacial drift. Note that in many cases, the upper trimline may have developed within an ice sheet that overtopped the highest summits (Figure 4(c)). From Ballantyne CK and Harris C (1994) *The Periglaciation of Great Britain*, Cambridge, UK. © Cambridge University Press, 1994. Reproduced with permission.

interpretation may be ambiguous (Figure 4), and further analyses are required. Such analyses fall into four categories: relative-age dating techniques, surface exposure dating using cosmogenic isotopes, relationship with other geomorphological evidence, and paleoglaciological considerations.

Relative-Age Dating of Trimlines

Relative-Age Dating of Bedrock Outcrops

The validity of trimlines mapped on the basis of geomorphological evidence has been assessed using three techniques that compare the weathering characteristics of bedrock outcrops

Figure 6 High-level ice-molded landscape at 900 m in the Western Grampian Highlands of Scotland. Rounded bedrock outcrops provide evidence of erosion by warm-based, sliding ice at the LGM, though some detachment of blocks by frost wedging after deglaciation is evident at the foot of the conspicuously rounded outcrop.

Figure 7 Unmodified periglacial landscape of shattered rock outcrops and regolith cover above the maximum level of Otira (LGM) glaciation, Torlesse Range, New Zealand.

Figure 8 Glacially transported perched boulder resting on granite blockfield debris at 796 m on Grytøya, northwest Norway.

above and below proposed trimlines: measurements of rock-surface roughness, Schmidt hammer measurements, and measurements of joint depths. All are based on the assumption that rock surfaces above trimlines have experienced much more prolonged weathering under periglacial conditions than rock surfaces affected by glacial abrasion at lower altitudes.

A microerosion meter was employed by [McCarroll and Nesje \(1993\)](#) to assess differences in rock-surface roughness on augen gneiss at sites above, between, and below two trimlines on Scåla (1843 m), a mountain in western Norway. Their findings indicated a significant increase in surface roughness above the lower trimline, but not across the higher. They concluded that the lower trimline probably represents the upper limit of Late Weichselian glacial abrasion, whereas the upper is of earlier origin. This technique is likely to be successful only for resistant lithologies that develop marked surface irregularities after prolonged exposure.

The Schmidt hammer is a device that records percentage rebound from rock surfaces to blows of constant force; for any lithology, weathered bedrock surfaces generally yield lower rebound values than fresh bedrock surfaces. In NW Scotland, [Ballantyne et al. \(1998\)](#) demonstrated significantly lower aggregate rebound values for quartzite and sandstone bedrock surfaces above mapped trimlines in comparison with those below trimlines ([Figure 9\(a\)](#)). In the same area, they found that the distribution of depths of horizontal stress-release joints exposed on rock faces above and below mapped trimlines differ ([Figure 9\(b\)](#)), with significantly deeper open joints above the trimlines. Both techniques have also been successfully employed to validate a trimline representing the upper limit of LGM glacial erosion in southwest Ireland ([Rae et al., 2004](#)). However, they require large numbers of measurements, and on many lithologies, intact outcrops are rare at above-trimline sites. Moreover, although the three techniques described earlier can be used to validate the geomorphological evidence for trimlines, they offer no conclusive evidence regarding trimline age or genesis.

Soil Weathering Characteristics

An alternative approach to relative-age dating of surfaces above and below proposed trimlines involves comparison of the weathering characteristics of soils. This approach assumes that glacial erosion removes pre-existing soils up to the level of LGM trimlines, so that soils above such trimlines exhibit evidence for more prolonged and advanced weathering than those below.

A method that has been widely employed in confirming mapped trimlines is X-ray diffraction (XRD) analyses of clay-fraction mineralogy of soils above and below mapped trimlines. [Ballantyne et al. \(1998\)](#) summarized the results of 128 analyses carried out on above-trimline and below-trimline soil samples obtained from mountains in northwest Scotland. Their results showed that for most common secondary clay mineral species, there is no difference in representation (presence or absence) above and below mapped LGM trimlines. However, gibbsite, a form of aluminum hydroxide that represents the end product of silicate alteration in a wide range of free-draining environments, is preferentially represented in above-trimline soils, at 78% of sites compared with 10%

below. The presence of gibbsite in samples from below the weathering limit may represent glacial reworking of gibbsitic soils. As gibbsite in Scottish montane soils is believed to be of pre-Devensian (pre-Weichselian) origin, its preferential representation above high-level trimlines indicates that such trimlines represent the upper limit of glacial erosion at the Devensian glacial maximum. Soil samples obtained by [Rae et al. \(2004\)](#) in southwest Ireland also exhibited significant differences in the composition of secondary clay minerals; they detected gibbsite in some above-trimline samples but none of the below-trimline samples.

[Marquette et al. \(2004\)](#) employed a wide range of soil weathering criteria to differentiate soils on blockfield-covered plateaus from those sampled from till and glacially eroded terrain in mountain areas of NE Quebec and Labrador. They demonstrated that the blockfield soils exhibit higher concentrations of crystalline iron and amorphous aluminum and silicium extracted with oxalate, indicating significantly greater weathering of soils above the blockfield limit. They also found that that secondary clay minerals (gibbsite and kaolinite) are also much more abundantly represented above the blockfield limit; gibbsite was detected only in the blockfield soils. They inferred from this evidence and associated cosmogenic isotope analyses that the blockfields probably survived several glacial events under a cover of cold-based ice. [Marquette et al. \(2004\)](#) inferred that the chemical and secondary clay mineral characteristics of blockfield soils on the mountains of northeast Québec and Labrador are “inherited from soil formed under a climate warmer than that prevailing today” (p. 31), and numerous other authors have concluded that the presence of secondary clay minerals in plateau-top regolith indicates inheritance from Neogene saprolite covers that have survived repeated Pleistocene glaciations under a protective cover of cold-based ice (e.g., [André, 2004](#); [Paasche et al., 2006](#)). [Goodfellow et al. \(2009\)](#), however, noted the potential for secondary clay mineralization and gibbsite formation in the early stages of silicate weathering and found only very limited evidence for chemical weathering in blockfield soils at a site in Sweden. It is possible that the secondary clay minerals detected in many blockfields are no older than the last interglacial and reflect regolith weathering under cool temperate or periglacial conditions ([Ballantyne, 2010b](#)).

Comparative analyses of soil weathering characteristics above and below trimlines are useful in identifying areas that escaped significant glacial erosion at the LGM, but do not allow differentiation of ice-marginal trimlines representing the maximum altitude of former ice cover and englacial trimlines representing the former boundary between cold-based and warm-based ice.

Environmental Magnetism

[Walden and Ballantyne \(2002\)](#) have explored the possibility of validating LGM trimlines on the premise that above-trimline soils with prolonged weathering histories may yield significantly different mineral magnetic signatures from those of post-deglaciation soils below trimlines. They found that concentration-dependent mineral magnetic parameters exhibit significant differences for soil samples above and below LGM trimlines, but that the nature of the difference is dependent on

Figure 9 (a) Schmidt hammer rebound response above and below a high-level trimline on sandstone terrain, northwest Scotland. (b) Depths of open (stress-release) joints above and below the same trimline. From Ballantyne CK, McCarroll D, Nesje A, Dahl SO, and Stone JO (1998) The last ice sheet in North-West Scotland: Reconstruction and implications. *Quaternary Science Reviews* 17: 1149–1184. © 1998 Elsevier Science Ltd. Reproduced with permission.

lithology. Basalt soil samples from above the LGM trimline on the Faroe Islands produced significantly higher concentration-dependent magnetic parameters than those below, probably reflecting more pronounced transformation of iron from non-magnetic to magnetic forms. Conversely, for sandstone soils in northwest Scotland, most concentration-dependent magnetic parameters proved significantly lower for samples above the trimline, probably reflecting loss of ferromagnetic minerals through dissolution and oxidation into antiferromagnetic forms. Significant differences in some mineral magnetic parameters were also detected by Rae et al. (2004) in their analyses of soil samples above and below an inferred LGM trimline in southwest Ireland. This approach has considerable promise for validating LGM trimlines, but does not by itself allow differentiation of hypotheses 1–3 above regarding trimline genesis.

Surface Exposure Dating Using Cosmogenic Isotopes

Dating the surface exposure age of bedrock or large boulders above and below mapped trimlines using cosmogenic isotope concentrations (commonly ^{10}Be , ^{26}Al , and ^{36}Cl) represents a powerful methodology not only for validating trimlines, but

also for determining their age and for discriminating between different hypotheses (1–4 above) of trimline origin. Exposure ages obtained from glacially eroded bedrock surfaces and erratic boulders below LGM trimlines should record the approximate timing of deglaciation, whereas those obtained from bedrock or boulders above trimlines should record ages that exceed the age ($\sim 26\text{--}21\text{ ka}$) of the LGM. Similarly, for younger trimlines cut by glaciers of Younger Dryas age, below-trimline surfaces should record ages $< \sim 11.7\text{ ka}$, whereas above-trimline surfaces should record the age ($< \sim 22\text{--}13\text{ ka}$) of earlier ice-sheet downwastage (Colledge et al., 2007).

Two potential drawbacks affect this approach. First, weathering of exposed rock surfaces results in erosional losses, so that measured exposure ages may slightly underestimate the true age of deglaciation. This problem is more acute for above-trimline surfaces where weathering under periglacial conditions has been prolonged, and for this reason, above-trimline exposure ages are generally regarded as minimal. Second, if below-trimline surfaces have not experienced sufficient (2–3 m) removal of rock by glacial erosion, they may retain residual concentrations of cosmogenic nuclides inherited from previous periods of exposure. Erratics and other glacially transported boulders may be similarly affected by complex exposure histories. This problem may be overcome by a careful selection

of bedrock sampling sites (e.g., on the plucked side of roches moutonnées), analyses of multiple samples to identify anomalies, and the use of two unstable isotopes with different half-lives (usually ^{10}Be and ^{26}Al) to establish whether their ratios indicate continuous exposure or complex exposure histories (e.g., Briner et al., 2003; Fabel et al., 2002; Marquette et al., 2004; Staiger et al., 2005; Sugden et al., 2005).

Despite these potential drawbacks, surface exposure dating using cosmogenic isotopes has proved robust not only in establishing the age of trimlines, but also in distinguishing ice-marginal trimlines cut around paleonunataks at the edge of former ice sheets from those representing a former englacial boundary between protective cold-based ice on high ground and erosive ice occupying adjacent valleys. Surface exposure ages obtained for paired above-trimline and below-trimline sites on mountains in Scotland and Ireland provide impressive vindication of the trimline concept: all the 21 samples collected from above-trimline bedrock outcrops or boulders yielded pre-LGM (>26 ka) ages, whereas all the 21 samples collected from ice-molded bedrock or large glacially deposited boulders below trimlines produced post-LGM (<21 ka) exposure ages (Figure 10). This contrast by itself, however, does not resolve the question of whether the trimlines in these areas reflect survival of unglacierized paleonunataks above the surface of the last British-Irish Ice Sheet, or preservation of glacially unmodified bedrock and boulders on high ground under a cover of cold-based ice that was frozen to the underlying substrate. Earlier work favored the first interpretation (e.g., Ballantyne et al., 1998), but the inferred ice-surface altitudes appear inconsistent with recent numerical ice-sheet models driven by proxy climate (Hubbard et al., 2009), evidence that the British-Irish Ice Sheet was much more extensive than previously believed and the presence on some mountains of above-trimline erratics. It now seems probable that most or all trimlines in the British Isles are of englacial origin (Ballantyne, 2010a) and that the areas of periglacial terrain above trimlines represent frozen-bed zones under the former ice sheet (Hall and Glasser, 2003; Kleman and Glasser, 2007), though trimlines delimiting the former maximum altitude of LGM ice may exist in southwest Ireland (Rae et al., 2004; Figure 11).

Elsewhere, however, surface exposure dating has been employed explicitly to test the competing validity of the nunatak hypothesis (Figure 4(a)) and englacial trimline hypothesis (Figure 4(c)). Fabel et al. (2002) employed paired analyses of ^{10}Be and ^{26}Al concentrations from erratics and glacially eroded bedrock on high-level relict surfaces in northern Sweden to demonstrate that these areas were ice-covered at the LGM and thus represent frozen-bed areas within the last Fennoscandian Ice Sheet. Similarly, Marquette et al. (2004) and Staiger et al. (2005) have resolved a long-standing debate on the significance of trimlines on the mountains of Labrador and northeast Quebec by showing that $^{26}\text{Al}/^{10}\text{Be}$ ratios for tors and blockfield boulders imply that these features survived the last and probably earlier glacial maxima under a protective cover of cold-based ice, a conclusion supported by the post-LGM ages of erratics located amid blockfield debris. A similar approach has been used by Sugden et al. (2005) to infer LGM and earlier ice cover on present-day nunataks in Marie Byrd Land, Antarctica (Figure 1). Briner et al. (2003) showed that erratics on weathered tors in eastern Baffin Island yield

exposure ages of 17–11 ka, whereas the tors themselves produced exposure ages >60 ka, demonstrating that the tors survived under a cover of cold-based ice at the LGM. Surface exposure ages obtained for tors on the Cairngorm Mountains of Scotland similarly indicate LGM ice cover despite extensive regolith cover on adjacent plateaus (Phillips et al., 2006). Conversely, Landvik et al. (2003) have employed surface exposure dating to argue that high ground in northwest Svalbard remained ice-free at the LGM, as glacial erratics and other boulders on blockfield-covered plateaus produced pre-LGM exposure ages, in contrast to the post-LGM exposure ages obtained for bedrock and erratic samples on low ground (Figure 12).

Geomorphological Evidence

Geomorphological evidence may, in some circumstances, allow conclusions to be drawn regarding the age and genesis of trimlines. In some cases, valley-side trimlines (Figure 2) may be continued downvalley by lateral moraines or drift limits, demonstrating that they mark the upper limit of coeval glaciation (e.g., Rae et al., 2004; Thorp, 1981, 1986). Consistent decline in trimline altitudes along former flowlines determined by striae, roches moutonnées, and streamlined bedforms also supports their interpretation as delimiting the upper surface of former ice masses but does not exclude an englacial interpretation. Several accounts also suggest that sharp trimlines defining an abrupt altitudinal contrast between ice-scoured and frost-weathered terrain are indicative of an ice-marginal rather than an englacial origin, as in the latter case, the gradual distribution of shear between sliding and cold-bed ice would be expected to produce a transition between weathering zones rather than a sharp boundary, though Marquette et al. (2004, Figure 3) illustrated that even englacial trimlines sometimes form distinct boundaries.

Paleoglaciological Considerations

A final test of the validity of ice-marginal interpretations of trimlines is reconstruction of the basal shear stress (τ_b) of reconstructed ice-surface profiles using

$$\tau_b = F(\rho gh \sin \alpha)$$

where ρ is ice density ($\sim 900 \text{ kg m}^{-3}$), g gravitational acceleration (9.81 m s^{-2}), h reconstructed ice thickness (m), α reconstructed ice-surface slope, and F is a form factor (Paterson, 1994). As glaciers moving over rigid beds yield $\tau_b = 40\text{--}140 \text{ kPa}$, the reconstructed shear stress should fall between these limits. Unfortunately, this constraint is probably too widely defined to prove conclusive in most cases. It is satisfied, for example, by most trimline altitudes and gradients in northwest Scotland (Ballantyne et al., 1998), but these probably represent englacial trimlines defining the altitudinal limit of erosion by warm-based sliding ice within an ice sheet that overtopped all mountains in the area (Ballantyne 2010a; Ballantyne and Hall, 2008). An additional constraint is that the altitudes of ice-marginal trimlines must be consistent with

Figure 10 Age–altitude plot of ^{10}Be and ^{36}Cl exposure ages obtained from above and below trimlines that mark the upper limit of glacially modified terrain and the lower boundary of blockfields and shattered bedrock outcrops on mountains in Scotland and Ireland. Horizontal lines represent $\pm 1\sigma$ external uncertainties. All above-trimline ages must be regarded as minima. From Ballantyne CK (2010) Extent and deglaciation chronology of the last British-Irish Ice Sheet: Implications of exposure dating using cosmogenic isotopes. *Journal of Quaternary Science* 25: 515–534. © 2009 John Wiley and Sons Ltd. Reproduced with permission.

the inferred lateral dimensions of former ice masses, particularly with climatic-proxy driven models of ice-sheet dynamics (e.g., Hubbard et al., 2009).

Conclusion

Periglacial (or glacial) trimlines have long been interpreted as representing the approximate upper limit of former glaciers or ice sheets. In many areas, however, it has now been demonstrated that tors, blockfields, and other weathering covers have been preserved under cold-based ice above the upper limit of erosion within a former ice sheet. Interpretation of trimlines as the upper limit of ice masses remains valid, but only if it can be demonstrated that they meet stringent criteria. The most important tests are (1) lack of erratics, perched glacially transported boulders, glacially detached blocks, and glacially modified tors above the trimline; (2) use of $^{26}\text{Al}/^{10}\text{Be}$ ratios to test for uninterrupted exposure of above-trimline boulder

and bedrock surfaces; (3) exposure dating of erratics and/or perched boulders to establish whether these were emplaced at the LGM or by an earlier, thicker ice sheet; and (4) consistency with other geomorphological evidence and the inferred lateral extent of former ice masses. Trimlines that satisfy these conditions permit a detailed reconstruction of former ice dimensions at the LGM in areas where nunataks remained above the ice surface at its maximum thickness, such as the Southern Alps of New Zealand (Figure 2) and Yosemite National Park in California (Figure 3). Trimlines cut across the flanks of paleonunataks and other valley-side slopes may also aid reconstruction of the former dimensions of glaciers that developed during later readvances of more limited extent, such as the outlet glaciers that developed in the Western Highlands of Scotland during the Younger Dryas Chron (e.g., Thorp, 1981, 1986). Conversely, where it can be demonstrated that tors, blockfields, and other weathering covers survived LGM ice cover above an englacial trimline, such evidence not only provides a minimum altitude for former ice cover but also

Figure 11 Trimline on Broaghnbinnia (745 m), southwest Ireland. The summit plateau supports a vegetated blockfield, but lower slopes comprise glacially scoured sandstone bedrock. The trimline separating these zones has been interpreted as representing the maximum altitude of the Cork–Kerry Ice Cap at the LGM, but may represent the uppermost limit of glacial erosion within a thicker ice mass that overtopped the mountain.

Figure 12 Topographic profiles of Amsterdamøya and Danskoøya in northwest Svalbard, showing locations and ^{10}Be exposure ages for samples from bedrock, erratic boulders, and blockfield boulders, and inferred maximum and minimum Late Weichselian ice-surface profiles. From Landvik JY, Brook EJ, Gualtieri L, Raisbeck G, Salvigsen O, and Yiou F (2003) Northwest Svalbard during the last glaciation: Ice-free areas existed. *Geology* 31: 905–908. © 2003 Geological Society of America. Reproduced with permission.

indicates the location of zones where cold-based ice remained frozen to the underlying substrate. Such evidence may throw light on the former subglacial thermal regime within ice sheets and the location and dimensions of former ice streams within ice sheets, thus permitting a much more detailed empirically based reconstruction of former ice-sheet history and dynamics than has hitherto proved possible (e.g., Hubbard et al., 2009; Sugden et al., 2005).

DEDICATIONS

The second edition of the *Encyclopedia of Quaternary Science* is dedicated to the memory of three outstanding scientists who have recently passed away: Russell Coope, Bill Watts, and Aleksis Dreimanis.

Russell Coope

G. Russell Coope (1930–2011) was essentially the founding father of Quaternary Entomology, having initiated the modern era of Quaternary insect fossil research in the late 1950s. Prior to that time, and going back to the nineteenth century, there had been a number of false starts and stops in this field. Previous researchers had assumed that any ice-age insect fossils they found would necessarily represent extinct taxa. This, as it turns out, was a completely false assumption. Beginning with the Late Pleistocene Upton Warren and Chelford sites, Russell was able to determine that fossil insects, especially beetles (Coleoptera) from Pleistocene deposits, represent extant species, albeit species that may live in dramatically different regions today than those where they lived in the past. For many years at the start of this endeavor, Russell was ‘a voice in the wilderness,’ having to convince colleagues in both the Quaternary sciences and modern Entomology that it is possible to identify ‘beetle bits’ (individual sclerites of beetle exoskeleton) to the species level, and that fossil beetle assemblages can yield reliable reconstructions of past environments. One of his greatest battles was to convince skeptical palynologists that the interstadial interval in what is now known as MIS 3, and another one toward the end of the last glaciation, were almost as warm as today, in spite of the fact that the vegetation cover represented in pollen records failed to register this. Likewise, Russell championed the idea that climate oscillations, particularly in the late glacial interval and early Holocene, were extremely rapid and dramatic: switching from full glacial to full interglacial conditions in a matter of decades, at most. Russell’s paleoclimate reconstructions were finally given full credence by the scientific community at large when the oxygen isotope records from Greenland ice cores began to be published, showing nearly the exact same amplitude and timing of climate change he had been publishing since the 1960s.

Russell’s research has had important implications for the field of zoogeography. On the basis of his work, we now know that insects respond to climate change chiefly by shifting their distributional ranges, so that they

Figure 1 Russell Coope at the Chelford quarry fossil site, August 1977. Photograph by Alan V. Morgan, used with permission.

track these changes through space. Through his tenacity and hard work, Russell was able to track down the modern ranges of beetle species he found in Pleistocene deposits to such remote locations as northeastern Siberia and the Tibetan Plateau (cold-adapted species), as well as North Africa and the Mediterranean islands (warm-adapted species).

Russell brought a level of curiosity and enthusiasm for natural history and all things scientific that was infectious. He was a brilliant lecturer and storyteller, holding his audiences practically spellbound. He trained many of the paleoentomologists who took the field forward in recent decades. His seemingly boundless energy kept him working and publishing papers, right up to the end of his life. He published more than 200 papers in his long career. He collaborated with dozens of other Quaternary scientists and was one of the first to appreciate and promote multidisciplinary studies of Pleistocene fossil sites. There is no doubt that his research and publishing legacies will continue to inspire future generations of paleoentomologists.

Bill Watts

William (Bill) A. Watts (1930–2010) was a towering figure in Quaternary paleoecology. He was a skilled botanist and ecologist and this was a secret to his success in unraveling the interglacial, late-glacial, and Holocene vegetation history not only in his native Ireland but also in the midwestern, the southeastern, and eastern USA, and in Italy. A major contribution was his reintroduction and development of quantitative plant macrofossil analysis. Macrofossils can often be identified to lower taxonomic levels than pollen, and Bill took full advantage of the complementarity of both methods. Thus, he was able to determine important features of vegetation history by identifying trees to species level and to illuminate the history of aquatic plants and local vegetational developments.

Figure 2 Photograph of Bill Watts, taken at Laguna de la Roya, Spain. Photograph by Fraser Mitchell, used with permission.

Bill always enjoyed fieldwork and microscope work, carrying out the latter in spare time left over from his job as Provost of Trinity College Dublin and his participation on committees dealing with hospitals and conservation in Ireland. Bill's quiet but intense enthusiasm and his great sense of humor added much to discussions, macrofossil identification sessions, and excursions with him. He and his work are inspirations to those who follow him.

Figure 3 Aleksis Dreimanis, photograph by Stephen Hicock.

Aleksis Dreimanis

Aleksis Dreimanis (1914–2011) was widely considered the world's foremost Quaternary glacial geologist in the 1970s and 80s. Aleksis was born in Latvia. While still an undergraduate at the University of Latvia, he published his first paper on the structural geology of deformed glacial deposits along the banks of the River Daugava – a study that he would return to and revise 60 years later. In 1944, Aleksis was conscripted as a military geologist by the Germans who occupied Latvia. For the next two years, he was separated from his family and forced to do strategic geological mapping in eastern Germany and northern Italy until the end of WWII, followed by internment in prisoner of war and displaced persons camps. In 1948, he escaped to London, England, where he met with the President of the University of Western Ontario who gave him a job in London, Canada (his family was able to join him the following year).

Over the next six decades at the University of Western Ontario, Aleksis ascended to the top of his discipline while gaining international recognition through landmark publications and inspired leadership on committees. His 1970s synthesis and definition of the Wisconsin Stage with Paul Karrow, Jan Terasmae, Dick Goldthwait, and Jane Forsyth became a world standard to which other records were compared. In 1989, he expanded this synthesis and introduced the conceptual till tetrahedron that showed the till continuum with end members occupying the corners of an inverted pyramid. He was among the first geologists to use radiocarbon dating, and he provided samples for inter-lab calibration. He was among the first to quantitatively study the relationship between till lithology and till formation, and to investigate how glacial transport and dynamics determine till texture, deformation, and rheologic states. Aleksis produced over 200 publications spanning eight decades and over a wide range of topics. Largely because of his influence, the study of till genesis and its relation to till properties and past glacial behavior has become a major focus of glacial geologic research in recent decades. The contribution and legacy that forms the body of work of Dreimanis will continue as a major benchmark within the diverse fields of scientific enquiry that are sometimes loosely referred to as 'glacial geology.'

FOREWORD

As with the publication of the first edition in 2007, the publication of the second edition of the *Encyclopedia of Quaternary Science* represents a landmark in the history of publishing in the field of Quaternary Science. Quaternary Science is a multidisciplinary endeavor which seeks to establish as detailed a picture as possible of the manifold environmental changes that have occurred during the most recent geological period, the Quaternary – an interval of time that spans the past 2.59 million years or the past 0.056% of geological time. It is a period of significant climate and environmental change and witnessed the widespread dispersal of our species, *Homo sapiens*, across the planet.

Since Louis Agassiz and Reverend William Buckland traipsed over parts of the Scottish landscape in 1840 in search of evidence of glaciation, a huge literature has emerged on the science of long-term climate and environmental change. Rapid technological advances in the late twentieth century and the proliferation of scientific journals, particularly in an era of electronic publishing, have resulted in an exponential growth and documentation of knowledge on the climate and environmental changes that have occurred during the Quaternary period. More recently, there has been an increasing public interest in applied Quaternary research as a framework for understanding the basis for recent climate changes and for understanding the nature and frequency of geological hazards and vexing issues such as soil erosion and land degradation, and the adverse effects of ocean water temperature increases and acidification on coral reef environments. In a similar manner, the likely magnitude of future sea-level rise and the associated impacts on coastal landscapes in the twenty-first century have attracted wide public interest. In this sense, Quaternary Science is very much on the political agenda and is a critically important subject to address issues of public concern.

The *Encyclopedia of Quaternary Science* edited by Scott Elias of Royal Holloway, University of London, UK, accordingly represents a particularly welcome addition to the literature. The encyclopedia presents an up-to-date and authoritative overview of Quaternary Science. The encyclopedia should enjoy a wide readership as the entries are presented in a very clear and easily readable style. The text of the articles is written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the field. Each entry of up to 4000 words covers the salient points of each topic with very clear illustrations. A central theme that pervades the work is the importance of Quaternary Science in providing an historical context for assessing present environmental changes and as basis for modeling potential future changes.

The encyclopedia consists of four volumes in print form and is available electronically. All the entries have been updated and the text totals around 3,500,000 words. As a major reference work, the encyclopedia has a very wide coverage of topics within the Quaternary sciences reflecting the complex and interdisciplinary nature of the science. Each of the major sections begins with a general overview of the topic prepared by a leading expert in the field. The major sections, for example, examine the analytical methods commonly used in paleoenvironmental reconstructions to unravel in a forensic-like manner the nature of former environments and the tempo of environmental change. Accordingly, a great range of topics such as the former extent of ice cover and nature of Quaternary glaciations, the biological responses and resultant fossil records to fluctuating climate, the expansion and contraction of desert environments, and global and local changes in relative sea levels are examined. Other topics covered include dating techniques, Quaternary stratigraphy, fluvial environments, lake level studies, paleosols, paleobotany, ancient DNA, paleolimnology, vertebrate studies, insect fossil studies, paleoceanography, stable isotope studies, ice core records, and human evolution in the Quaternary. One of the new sections in the encyclopedia examines the application of Quaternary proxy evidence in forensic science. All sections provide a clear summary of the latest advances in the fields of research.

This is an outstanding work and the editors and the publisher are to be congratulated for producing an encyclopedia that cogently summarizes the current state of the science.

INTRODUCTION

It has been my privilege to work with more than 420 leading Quaternary scientists in developing the second edition of the *Encyclopedia of Quaternary Science*. This team of writers and editors represents 28 countries in Europe, Asia, Africa, the Americas, Australia, and New Zealand. Starting with the first edition in 2006, I have had my finger on the pulse of Quaternary science, and this branch of science is truly pulsating! Information now comes from an incredible variety of disciplines: geochemistry, numerical modeling, history, vulcanology, paleobiology, nuclear physics, stratigraphy, sedimentology, climatology, anthropology, archaeology, glacial geology, soil science, ice-stream modeling – the list is staggering. This highly disparate group of people are bound together by one common thread: the desire to know the history of the planet during the last 2.6 million years – the time of the ice ages. For Quaternary scientists, this is a pressing need, not an idle curiosity. Any doubts about this statement can be easily dispelled by a consideration of the lengths to which many of them go to gather the necessary data. Some of them have worked for months in sub-zero temperatures on top of very high mountains, or near the center of polar ice sheets, collecting ice cores. Others have spent many weeks on some of the roughest seas in the world, drilling deep-sea sediment cores. Often the work is more mundane. An oxygen isotope curve for a lengthy marine sediment core represents thousands of hours of patiently picking tiny fossils from layer after layer of sediments, in order to obtain sufficient numbers of calcium carbonate shells to yield samples for isotopic analysis. A map showing proposed ice limits from the last glaciation represents thousands of hours of field mapping of glacial features by dozens of people. Why do all of these people devote their lives to this pursuit of knowledge? Does it really matter so much? The answer becomes clear when you step back and examine the topic of Quaternary science in its proper context.

The world we inhabit has largely been shaped by the events of the Quaternary. All the biological communities that exist today are the end product of a long series of species associations that came together in the past, largely driven by climatic change during the Pleistocene. We cannot properly understand the functioning of modern ecosystems without a solid knowledge of their history, any more than we can understand the plot of a long novel by reading just the final page. We are also living in a time of alarming climate changes. Even though the pace and intensity of some of these changes have not been seen in historical times, there were many rapid, large-scale climatic shifts in the Pleistocene. The best way to predict the effects of global warming on the planet's climate and ecosystems is to look at the history of similarly intense, rapid changes in the prehistoric past. The interval that is most relevant today is the most recent geologic period: the Quaternary. As human populations rise exponentially, increasing numbers of people are exposed to geologic hazards, such as earthquakes (and attendant tsunamis), and volcanic eruptions. These are short-lived events that take place only rarely in any one region. The interval between major events, such as volcanic eruptions, may be centuries or millennia. How do we come to grips with predicting the future likelihood of such erratic phenomena? Again, the answers come from piecing together the ancient history of such events, over many thousands of years.

The Quaternary has been the time when our own species came of age. The beginning of the Quaternary, roughly 2.6 million years ago, was about the time when the earliest member of our genus (*Homo*) first appeared in Africa. Pleistocene environments shaped the course of human evolution, culminating in anatomically modern *Homo sapiens* spreading from Africa throughout most of the world during the last glaciation. Even though human beings largely shape their own environments today, for the vast majority of our species' history, it has been the environment that has shaped us. Our direct ancestors' adaptations to environmental change are deeply ingrained in our genes. Thus, an understanding of the environmental conditions that shaped our species is critical to our understanding of humanity.

Quaternary science is a rapidly changing field, and the articles that appear in this encyclopedia reflect this. New dating techniques, such as cosmogenic nuclide dating, are revolutionizing our understanding of many earth surface processes. The ability to analyze increasingly smaller samples for radiocarbon and stable isotopes of oxygen and hydrogen means that we are gaining a level of precision in the reconstruction of past events that was unheard of just a few years ago. Stable isotope studies of air bubbles trapped in ice cores from Greenland and Antarctica have given Quaternary scientists an entirely new perspective on the rapidity and intensity of climatic change during the last glacial cycle and beyond. Likewise, the discovery of long sequences of annually laminated sediments in both marine and freshwater environments has provided a great leap forward in our ability to resolve the timing of environmental changes in nonpolar regions. The ability to extract and analyze ancient DNA sequences from Pleistocene fossils (both plants and animals) is revolutionizing the field of paleobiology. We are beginning to be able to trace the genetic lineages of a number of different organisms, from beetles to bison. In short, these are very exciting times to be a Quaternary scientist! While it is virtually impossible for any Quaternary researcher or student to keep abreast of all the new discoveries in this multifaceted science, this encyclopedia can be of great help. The articles contained here represent the state of the art in a huge variety of topics, and they offer the opportunity to dig deeper into their respective subjects by providing full citations of the most pertinent literature available. I invite you to come and explore the Quaternary Period in the pages that follow. It is a fascinating story.

HOW TO USE THE ENCYCLOPEDIA

The material in this encyclopedia is organized into two broad sections. At the start of Volume 1 are four *Introductory Articles* that serve as a broad introduction to the field. It is intended that these articles should serve as the first port of call for readers, to enable them to embark on any of the main entries without the need to consult other material beforehand.

Following the Introductory Articles, the main body of The Encyclopedia is arranged as a series of entries in alphabetical order. These entries fill the remainder of the volumes.

To help realize the full potential of the material in the Encyclopedia we have provided four features to help you find the topic of your choice: a contents list by subject; an alphabetical contents list; cross-references to other articles; and a full subject index.

1. Contents list by subject

Your first point of reference will probably be the contents list by subject. This list appears at the front of each volume, and groups the entries under subject headings describing the broad themes of Quaternary science. This will enable the reader to make quick connections between entries and to locate the entry of interest. Under each main section heading, you will find several subject areas and under each subject area is a list of those entries that covers aspects of that subject, together with the volume and page numbers on which these entries may be found.

2. Alphabetical contents list

The alphabetical contents list, which also appears at the front of each volume, lists the entries in the order in which they appear in the Encyclopedia. This list provides both the volume number and the page number of each entry.

You will find ‘dummy’ entries where obvious synonyms exist for entries or where we have grouped together related topics. Dummy entries appear in both the contents list and the body of the text.

Example

If you were attempting to locate material on *peat studies* via the alphabetical contents list:

PEAT STUDIES *see* PLANT MACROFOSSIL METHODS AND STUDIES: Mire and Peat Macros

The dummy entry directs you to the entry in which *peat* is covered.

If you were trying to locate the material by browsing through the text and you had looked up *Peat Studies*, then the following information would be provided in the dummy entry:

Peat Studies *see* PLANT MACROFOSSIL METHODS AND STUDIES: Mire and Peat Macros

3. Cross-references

All of the entries in the Encyclopedia have been extensively cross-referenced. The cross-references, which appear at the end of the entry, serve three different functions:

- i. To indicate if a topic is discussed in greater detail elsewhere.
- ii. To draw the reader’s attention to parallel discussions in other entries.
- iii. To indicate material that broadens the discussion.

Example

The following list of cross-references appear at the end of the entry GLACIAL LANDFORMS, ICE SHEETS | Growth and Decay

See also: **Introduction:** History of Quaternary Science; **Paleoclimate Reconstruction:** Sub-Milankovitch (DO/Heinrich) Events; **Glacial Climates:** Thermohaline Circulation; **Glaciation, Causes:** Astronomical Theory of Paleoclimates; **Paleoclimate Modeling:** Last Glacial Maximum GCMs; **Glaciations:** Overview; **Sea Level Studies:** Overview; Paleocceanography; **Ice Core Records:** Correlations Between Greenland and Antarctica.

Here you will find examples of all three functions of the cross-reference list: a topic discussed in greater detail elsewhere (e.g., **Paleoclimate Modeling:** Last Glacial Maximum GCMs), parallel discussion in other entries (e.g., **Glacial Climates:** Thermohaline Circulation), and reference to entries that broaden the discussion (e.g., **Glaciations:** Overview).

4. Index

The index provides you with the page number where the material is located. The index entries differentiate between material that is a whole entry, is part of an entry, or is data presented in a figure or a table. Detailed notes are provided on the opening page of the index.

5. Contributors

A full list of contributors is listed at the beginning of each volume.

CONTENTS LIST BY SUBJECT

Location references refer to the volume number and page number (separated by a colon)

Introduction and History of Science

INTRODUCTION | History of Quaternary Science, 1:1
INTRODUCTION | History of Dating Methods, 1:9
INTRODUCTION | Societal Relevance of Quaternary Research, 1:17
INTRODUCTION | Understanding Quaternary Climatic Change, 1:26

Paleoclimatology

Overview and Approaches

PALEOCLIMATE | Introduction, 3:87
PALEOCLIMATE RECONSTRUCTION | Approaches, 3:179
PALEOCLIMATE MODELING | Data-Model Comparisons, 3:135
PALEOCLIMATE | Timescales of Climate Change, 3:93
PALEOCLIMATE | Modern Analog Approaches in Paleoclimatology, 3:102
PALEOCLIMATE | Paleoclimate History of the Arctic, 3:113
PALEOCLIMATE | The Younger Dryas Climate Event, 3:126

Paleoclimate Reconstructions

PALEOCLIMATE RECONSTRUCTION | Pliocene Environments, 3:185
GLACIATION, CAUSES | Tectonic Uplift and Continental Configurations, 2:127
GLACIATION, CAUSES | Astronomical Theory of Paleoclimates, 2:136
PALEOCLIMATE RECONSTRUCTION | Paleodroughts and Society, 3:194

SEA LEVEL STUDIES | Sedimentary Indicators of Relative Sea-Level Changes – Low Energy, 4:396
SEA LEVEL STUDIES | Microfossil-Based Reconstructions of Holocene Relative Sea-Level Change, 4:419
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Relative Sea-Level Changes in High Latitudes, 4:467
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Sea-Level Changes in Greenland, 4:481
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Relative Sea-Level Changes at Mid-Latitudes, 4:489
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Relative Sea-Level Changes in the Tropics, 4:495
SEA-LEVELS, LATE QUATERNARY | Tectonics and Relative Sea-Level Change, 4:503

Paleosols and Wind-Blown Sediments

Paleosol Research

PALEOSOLS AND WIND-BLOWN SEDIMENTS | Overview, 3:357
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Nature of Paleosols, 3:367
LOESS DEPOSITS: ORIGINS AND PROPERTIES, 2:573
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Weathering Profiles, 3:392
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Soil Micromorphology, 3:381
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Soil Morphology in Quaternary Studies, 3:402
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Mineral Magnetic Analysis, 3:375
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Biogeochemical Role of Dust in Quaternary Climate Cycles, 3:412

Dune Studies

DUNE FIELDS | High Latitudes, 1:597
DUNE FIELDS | Mid-Latitudes, 1:606
DUNE FIELDS | Low Latitudes, 1:623

Loess Studies

LOESS RECORDS | Central Asia, 2:585
LOESS RECORDS | China, 2:595
LOESS RECORDS | Europe, 2:606
LOESS RECORDS | North America, 2:620
LOESS RECORDS | South America, 2:629
EOLIAN RECORDS, DEEP-SEA SEDIMENTS, 1:637

Lake Level Studies

LAKE LEVEL STUDIES | Overview, 2:483
LAKE LEVEL STUDIES | Modeling, 2:558
LAKE LEVEL STUDIES | Africa during the Late Quaternary, 2:499
LAKE LEVEL STUDIES | Asia, 2:506
LAKE LEVEL STUDIES | Australia, 2:524
LAKE LEVEL STUDIES | Latin America, 2:531
LAKE LEVEL STUDIES | North America, 2:537
LAKE LEVEL STUDIES | West-Central-Europe, 2:549

Paleobotany

Overview

PALEOBOTANY | Overview of Terrestrial Pollen Data, 2:699

Pollen Studies

POLLEN ANALYSIS, PRINCIPLES, 3:794
POLLEN METHODS AND STUDIES | Use of Pollen as Climate Proxies, 3:805
POLLEN METHODS AND STUDIES | Surface Samples and Trapping, 3:839
POLLEN METHODS AND STUDIES | The Biome Approach to Reconstructing Past Vegetation, 3:861
POLLEN METHODS AND STUDIES | POLLSCAPE Model, 3:871
POLLEN METHODS AND STUDIES | Reconstructing Past Biodiversity Development, 3:816
POLLEN METHODS AND STUDIES | Numerical Analysis Methods, 3:821
POLLEN METHODS AND STUDIES | Changing Plant Distributions and Abundances, 3:854
POLLEN METHODS AND STUDIES | Stand-Scale Palynology, 3:846
PALEOBOTANY | Paleophytogeography, 2:730
POLLEN METHODS AND STUDIES | Databases and Their Application, 3:831

Charred Particle Analysis

PALEOBOTANY | Charred Particle Analyses, 2:716

Quaternary Pollen Records

POLLEN RECORDS, LAST INTERGLACIAL OF EUROPE, 4:1
POLLEN RECORDS, LATE PLEISTOCENE | Africa, 4:9
POLLEN RECORDS, LATE PLEISTOCENE | Australasia, 4:18
POLLEN RECORDS, LATE PLEISTOCENE | Northern Asia, 4:27

POLLEN RECORDS, LATE PLEISTOCENE | Northern North America, 4:39
 POLLEN RECORDS, LATE PLEISTOCENE | Western North America, 4:72
 POLLEN RECORDS, LATE PLEISTOCENE | South America, 4:52
 POLLEN RECORDS, LATE PLEISTOCENE | Middle and Late Pleistocene in Southern Europe, 4:63
 POLLEN RECORDS, POSTGLACIAL | Africa, 4:85
 POLLEN RECORDS, POSTGLACIAL | Australia and New Zealand, 4:104
 POLLEN RECORDS, POSTGLACIAL | Northeastern North America, 4:115
 POLLEN RECORDS, POSTGLACIAL | Northwestern North America, 4:124
 POLLEN RECORDS, POSTGLACIAL | Southeastern North America, 4:133
 POLLEN RECORDS, POSTGLACIAL | Southwestern North America, 4:142
 POLLEN RECORDS, POSTGLACIAL | South America, 4:156
 POLLEN RECORDS, POSTGLACIAL | Northern Asia, 4:164
 POLLEN RECORDS, POSTGLACIAL | Northern Europe, 4:173
 POLLEN RECORDS, POSTGLACIAL | Southern Europe, 4:179
 POLLEN METHODS AND STUDIES | Archaeological Applications, 3:880

Phytoliths

PHYTOLITHS, 3:582

Ancient Plant DNA

PALEOBOTANY | Ancient Plant DNA, 2:705

Plant Macrofossil Studies

PLANT MACROFOSSIL INTRODUCTION, 3:593
 PLANT MACROFOSSIL METHODS AND STUDIES | Surface Samples, Taphonomy, Representation, 3:684
 PLANT MACROFOSSIL METHODS AND STUDIES | Treeline Studies, 3:690
 PLANT MACROFOSSIL METHODS AND STUDIES | Megafossils, 3:621
 PLANT MACROFOSSIL METHODS AND STUDIES | Paleolimnological Applications, 3:657
 PLANT MACROFOSSIL METHODS AND STUDIES | CO₂ Reconstruction from Fossil Leaves, 3:613
 PLANT MACROFOSSIL METHODS AND STUDIES | Rodent Middens, 3:674

PLANT MACROFOSSIL METHODS AND STUDIES | Mire and Peat Macros, 3:637
 PLANT MACROFOSSIL METHODS AND STUDIES | Use in Environmental Archaeology, 3:699
 PLANT MACROFOSSIL METHODS AND STUDIES | Dendroarchaeology, 3:630
 PLANT MACROFOSSIL METHODS AND STUDIES | Validation of Pollen Studies, 3:725

Plant Macrofossil Records

PLANT MACROFOSSIL RECORDS | Arctic Eurasia, 3:733
 PLANT MACROFOSSIL RECORDS | Greenland, 3:760
 PLANT MACROFOSSIL RECORDS | Arctic North America, 3:746
 PLANT MACROFOSSIL RECORDS | Holocene North America, 3:768
 PLANT MACROFOSSIL RECORDS | Late Glacial Multidisciplinary Studies, 3:785

Diatom Studies

DIATOM INTRODUCTION, 1:471
 DIATOM METHODS | Data Interpretation, 1:489
 DIATOM RECORDS | North Atlantic and Arctic, 1:562
 DIATOM RECORDS | Pacific, 1:571
 DIATOM RECORDS | Antarctic Waters, 1:527
 DIATOM RECORDS | Diatom Fossil Records from Marine Laminated Sediments, 1:554
 DIATOM RECORDS | Freshwater Laminated Sequences, 1:540
 DIATOM RECORDS | Large Lakes, 1:546
 DIATOM METHODS | Salinity and Climate Reconstructions from Continental Lakes, 1:507
 DIATOM METHODS | $\delta^{18}\text{O}$ Records, 1:481
 PALEOBOTANY | Silicon Isotopes in Diatoms, 2:734
 DIATOM METHODS | Use in Archaeology, 1:516
 DIATOM METHODS | Diatomites: Their Formation, Distribution, and Uses, 1:501
 Structures and Applications of Biomarkers from Arctic Sea Ice Diatoms, 1:588

Paleolimnology

PALEOLIMNOLOGY | Overview of Paleolimnology, 3:259
 PALEOLIMNOLOGY | Lake Chemistry, 3:292
 PALEOLIMNOLOGY | Physical Properties of Lake Sediments, 3:300
 PALEOLIMNOLOGY | Cladocera, 3:271
 PALEOLIMNOLOGY | Freshwater Mollusks, 3:281

PALEOLIMNOLOGY | Contributions of
Paleolimnological Research to
Biogeography, 3:313
PALEOLIMNOLOGY | Pigment Studies, 3:326
PALEOLIMNOLOGY | Visible and Infrared
Spectroscopical Applications, 3:349
PALEOLIMNOLOGY | Multiproxy Approaches, 3:339

Vertebrate Studies

VERTEBRATE OVERVIEW, 4:590
VERTEBRATE RECORDS | Early Pleistocene, 4:599
VERTEBRATE RECORDS | Early and Middle
Pleistocene of Northern Eurasia, 4:605
VERTEBRATE RECORDS | Mid-Pleistocene of
Southern Asia, 4:651
VERTEBRATE RECORDS | Mid-Pleistocene of
Africa, 4:615
VERTEBRATE RECORDS | Mid-Pleistocene of
Australia, 4:621
VERTEBRATE RECORDS | Mid-Pleistocene of
Europe, 4:639
VERTEBRATE RECORDS | Mid-Pleistocene of
North America, 4:646
VERTEBRATE RECORDS | Late Pleistocene of
Africa, 4:664
VERTEBRATE RECORDS | Late Pleistocene of North
America, 4:673
VERTEBRATE RECORDS | Late Pleistocene of South
America, 4:680
VERTEBRATE RECORDS | Late Pleistocene of
Southeast Asia, 4:693
VERTEBRATE RECORDS | Late Pleistocene
Megafaunal Extinctions, 4:700
VERTEBRATE RECORDS | Late Pleistocene
Mummified Mammals, 4:713
VERTEBRATE STUDIES | Ancient DNA, 4:719
VERTEBRATE STUDIES | Speciation and
Evolutionary Trends in Quaternary
Vertebrates, 4:723
VERTEBRATE STUDIES | Dwarfing and Gigantism in
Quaternary Vertebrates, 4:733
VERTEBRATE STUDIES | Interactions with
Hominids, 4:748

Insect Fossil Studies

Beetle Studies

BEETLE RECORDS | Overview, 1:161
BEETLE RECORDS | Late Tertiary and Early
Quaternary Records, 1:173
BEETLE RECORDS | Middle Pleistocene of Western
Europe, 1:184

BEETLE RECORDS | Late Pleistocene of
Europe, 1:200
BEETLE RECORDS | Late Pleistocene of North
America, 1:221
BEETLE RECORDS | Late Pleistocene of South
America, 1:235
BEETLE RECORDS | Late Pleistocene of
Australia, 1:191
BEETLE RECORDS | Late Pleistocene of Northern
Asia, 1:255
BEETLE RECORDS | Late Pleistocene of Japan, 1:207
BEETLE RECORDS | Late Pleistocene of New
Zealand, 1:244
BEETLE RECORDS | Postglacial Europe, 1:274
BEETLE RECORDS | Postglacial North America, 1:282

Chironomid Studies

CHIRONOMID RECORDS | Chironomid
Overview, 1:355
CHIRONOMID RECORDS | Late Pleistocene of
Europe, 1:373
CHIRONOMID RECORDS | Africa, 1:361
CHIRONOMID RECORDS | Late Pleistocene of
Europe, 1:373
CHIRONOMID RECORDS | Postglacial
Europe, 1:386
CHIRONOMID RECORDS | Postglacial Southern
Hemisphere, 1:398

Oribatid Mite Studies

ORIBATID MITES, 2:680

Paleoceanography

Paleoceanographic Studies

PALEOCEANOGRAPHY | Paleoceanography An
Overview, 2:745
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Corals, Sclerosponges and Mollusks, 2:795
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Benthic Foraminifera, 2:765
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Planktic Foraminifera, 2:825
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Radiolarians and Silicoflagellates, 2:830
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Coccolithophores, 2:783
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Alkenone Paleothermometry Based on the
Haptophyte Algae, 2:755
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Marine Diatoms, 2:816

This article is reproduced from the previous edition, volume 2, pp. 904–909, © 2007, Elsevier B.V.

Introduction

Different processes of erosion, weathering, and transport leave distinctive morphological signatures on sedimentary particles. By associating particular morphologies with particular processes, clast form analysis can be used to reconstruct aspects of debris history, and to shed light on the significance and context of sediment facies. Clast form analysis has been part of the standard toolkit of sedimentologists for many decades, and a broad range of techniques and approaches has been developed. As a result, the literature is large, diverse, and often confusing. An excellent review of the early literature on clast form analysis was provided by [Barrett \(1980\)](#), and a detailed description of field techniques and analytical methods has been presented by [Benn \(2004\)](#). Clast form analysis refers to the study of pebble-sized or larger particles. Analysis of the form of sand-sized or smaller particles is known as micromorphological analysis.

Defining Particle Form

Like every snowflake, every sedimentary particle has a unique form and a unique story to tell. To extract the maximum amount of useful information from this boundless variety, it is useful to think of clast form in terms of a simple hierarchy of measurable characteristics ([Barrett, 1980](#)). Shape, the first-order property, refers to the overall proportions of the particle; roundness, the second-order property, describes the degree of rounding of the particle outline; and texture, the third-order property, concerns its surface characteristics. Conceptually,

these are quite separate properties, although in practice there tend to be consistent associations of shape, roundness, and textural characteristics in clasts with similar histories.

Shape

Shape is defined in terms of the relative dimensions of the long-, intermediate-, and short-particle axes (a , b , c , or L , I , S , respectively). This definition of shape reduces all the craggy detail of individual clasts to simple cuboids, which can be visualized as the smallest box that the particle can be fitted into. All possible shapes form a continuum between three end members: (i) cubic, or equant particles with all three axes of equal length ($a=b=c$); (ii) slabby, or platy particles with the a - and b -axes equal and a very small c -axis ($a=b \gg c$); and (iii) rod-shaped particles with the a -axis much longer than the other two ($a \gg b=c$). This continuum is illustrated in [Figure 1](#), in which all possible cuboidal shapes are represented on an isometric triangular diagram known as the general shape triangle ([Benn and Ballantyne, 1993](#); [Sneed and Folk, 1958](#)). The ratios between the short and long axes ($c:a$) and the intermediate and long axes ($b:a$) form the scales on two sides of the triangle. These two ratios are enough to uniquely define the shape of any cuboid, although other indices of particle shape can be used as additional scales if desired (e.g., [Benn and Ballantyne, 1993](#)). Examples of other potentially useful indices include the disk-rod index (DRI: $(a-b)/(a-c)$), which distinguishes disk- and rod-shaped clasts; and maximum projection sphericity (MPS: $3\sqrt{(c^2/ab)}$), which reflects the balance of drag and gravitational forces acting on a particle immersed

Figure 1 General shape triangle, showing the three-way continuum of clast shapes. Adapted from [Sneed ED and Folk RL \(1958\)](#) Pebbles in the lower Colorado River, Texas, a study in clast morphogenesis. *Journal of Geology* 66: 114–150.

in a fluid. MPS is a good index of the behavior of clasts transported by or settling in, water but is of limited usefulness outside this hydraulic context. A useful spreadsheet program for plotting particle shape data on triangular diagrams has been created by [Graham and Midgley \(2001\)](#).

Roundness

Roundness can be assessed using a variety of approaches. Several quantitative methods have been proposed based on the radius of curvature of particle edges. For example, the Wentworth–Cailleux index ($2000r/a$), compares the radius of curvature of the sharpest edge of the clast (r) with its longest dimension (a). Values of r can be determined from templates, although in practice radii are very difficult to determine for clasts with sharp, unworn edges. Another problem with this approach is that the sharpest edge may not be representative of the roundness of the particle as a whole (as is likely to be the case for rounded clasts that have been broken). For this reason, most researchers use semiquantitative methods, which assign particles to roundness categories using comparison charts or descriptive criteria. [Figure 2](#) shows a widely used comparison chart, in which roundness categories are represented by sets of images. An alternative approach is to employ descriptive criteria as the basis for assigning clasts to a roundness category ([Table 1](#)). Such criteria provide an objective basis for classification, which can be quickly and easily applied in the field. However, as with all roundness classification schemes, it attempts to divide continuous variation into mutually exclusive categories, and different operators may put the class boundaries in different places. Care must be taken to ensure consistency and minimize operator bias, perhaps by keeping a collection of ‘reference clasts’ for comparison.

Figure 2 Comparison chart showing nine numerical categories of particle roundness. Adapted from [Krumbein WC \(1941\)](#) Measurement and geological significance of shape and roundness of sedimentary particles. *Journal of Sedimentary Petrology* 11: 64–72.

Texture

Surface texture is an underused source of information, and few systematic studies have been conducted to date. However, certain textures (such as striated surfaces) provide unambiguous records of particular transport and weathering processes, and thus amply repay the investment of time spent recording them. A simple but effective approach is to assign clasts to nominal categories and count frequencies of occurrence. Such categories could include: fresh, unworn fracture surfaces; rough, weathered surfaces; polish; striations; crescentic or conchoidal fractures on polished pebbles, which may indicate high impact forces in shoreface environments; and ventifacts, recording polishing by wind-blown sand.

This list of categories is not exhaustive, and variations can be devised depending on the purpose of the investigation.

Field Measurements

Clast form measurements are usually made in the field, using samples of clasts taken from individual landforms or sediment facies. Normally, each sample comprises 50 clasts, although some investigators take larger or smaller samples. Objective interpretation of sample characteristics can only be accomplished with reference to deposits of known origin, and sampling schemes should therefore include control samples

Table 1 Descriptive clast roundness categories

<i>Class</i>	<i>Description</i>
Very angular (VA)	Edges and faces unworn; sharp, delicate protuberances
Angular (A)	Edges and faces unworn
Subangular (SA)	Faces unworn, edges worn
Subrounded (SR)	Edges and faces worn but clearly distinguishable
Rounded (R)	Edges and faces worn and barely distinguishable
Well rounded (WR)	No edges or faces distinguishable

representing a range of process domains. Well-chosen control samples provide unambiguous baselines against which other samples can be compared, so research design should be informed by a thorough understanding of the system under investigation. For example, where the transport history of glaciogenic sediments is of interest, control samples might include supraglacial debris, basal debris-rich ice, sediments in glaciofluvial transport, and so on, encompassing the range of possible transport paths taken by debris in the catchment. Where the relevant processes are no longer active, such as in deglaciated regions, sediment facies of known origin can be used as proxies. For example, glaciofluvial bedload may be represented by river gravels, supraglacial debris by scree, basal ice by till, and so on. Any errors in the interpretation of such proxies, however, will be propagated throughout the investigation, so great care must be taken with this fundamental aspect of research design. Pilot studies may help to optimize sampling strategies. A range of summary statistics can be used to characterize data distributions and compare groups of samples. These include (i) sample means and standard deviations; (ii) medians and interquartile ranges; and (iii) percentages of data values above or below some reference point. Where particle shape and/or roundness data are not normally distributed, means and standard deviations are inappropriate measures of central tendency and dispersion, so nonparametric statistics ((ii) and (iii)) provide the most flexible means of summarizing and comparing samples. The covariance of two clast form indices provides a more powerful means of characterizing the aggregate particle form characteristics of samples than single indices used in isolation (Benn and Ballantyne, 1994).

Influences on Particle Form

Lithology

Clast form characteristics interpreted with reference to control samples can be used to reconstruct weathering histories, transport paths, and certain depositional and postdepositional processes. Clast form, however, is also strongly influenced by parent lithology. The spacing and distribution of bedding planes, joints, or other discontinuities predetermine lines of fracture and, therefore, influence particle shape. Thin-bedded sandstones and shales, for example, tend to form platy clasts, whereas massive crystalline rocks such as granites, gneiss, and gabbro tend to produce more equant particles. Additionally, rock hardness affects the susceptibility of particles to rounding processes. It is necessary, therefore, to control for lithology

**Figure 3** Striated and faceted clasts from subglacial till.

when sampling, either by limiting measurements to single lithologies if transport processes are of interest, or limiting measurements to single process domains if the influence of lithology is being investigated.

Weathering

Weathering processes can affect particle form in several ways. Macrogelivation (frost shattering) tends to produce angular and very angular clasts, whereas microgelivation (granular disintegration) tends to increase particle roundness by preferentially weathering particle edges. Macrogelivation also affects surface texture by exposing fresh, unweathered surfaces and affects shape by changing the relative dimensions of particle axes, whereas microgelivation produces rough, weathered surfaces but tends to leave overall shape unchanged. Radius of curvature of the edges of granite boulders can be used as a proxy for time elapsed since deposition, on the assumption that radius increases as microgelivation proceeds.

Transport

Transport processes can leave a variety of imprints on sedimentary particles. Some high-energy processes, such as rockfall and avalanching, cause clast fracturing, altering shape characteristics and increasing angularity. Clasts transported by snow avalanches tend to have particularly high angularity due to very large interparticle impact forces. Conversely, abrasion in fluvial and coastal environments increases particle roundness, ultimately producing well-rounded, egg-shaped clasts. Transport in subglacial shear zones at or close to the ice–bed interface produces very distinctive clast morphologies by a combination of fracture and abrasion. Asymmetric application of stresses in subglacial shear zones means that abrasion is focused on the top and upglacier-facing (stoss) surfaces, whereas fracturing preferentially occurs on downglacier-facing (lee) surfaces. This produces characteristic asymmetric clast forms known as ‘flat-irons,’ ‘stoss–lee forms,’ or ‘bullet-shaped clasts’ (Sharp, 1982; Figure 3). Krüger (1984) has described ‘double stoss–lee forms,’ which he attributed to a two-stage process of ploughing followed by lodgement. The asymmetry of clasts shaped during subglacial transport and deposition contrasts with the symmetrical or isotropic wear patterns typical of clasts modified by fluvial and shoreface processes.

Some low-energy processes, such as hillslope creep, debris flow, and englacial or supraglacial transport, may have little or no effect on particle shape, and clasts transported by such

Figure 4 (a) Shape (triangular diagrams) and roundness data (histograms) for till and scree deposits in Jotunheimen, Norway. The clast shape index (C_{40} ; % of clasts with $c:a=0.4$) is high for scree (numerous slabby and elongate shapes) and low for till clasts (numerous blocky shapes); the roundness index (RA; % of angular and very angular clasts) is high for scree and low for till samples. (b) Covariance of C_{40} and RA for control and moraine samples. The moraine samples form a band between the supraglacial and till controls, suggesting that they comprise mixtures of debris from active and passive transport paths. Adapted from [Benn DI and Ballantyne CK \(1994\)](#) Reconstructing the transport history of glacial sediments: A new approach based on the co-variance of clast form indices. *Sedimentary Geology* 91: 215–227.

processes tend to retain characteristics developed during earlier events. Evidence for a lack of modification can, therefore, provide as much information as evidence for particular processes. For example, Boulton (1978) distinguished two contrasting modes of glacial transport: active transport at or close to the bed, and passive transport at higher levels in or on the ice. As already noted, active transport results in clast fracture and abrasion, whereas passively transported debris tends to have shape, roundness, and textural properties inherited from earlier phases of weathering and transport, such as macrogelivation and avalanching. Benn and Ballantyne (1994) found that actively and passively transported clasts can be differentiated using the covariance of their shape and roundness characteristics, providing an efficient means of identifying their relative abundances in glacial deposits and thus the relative importance of different transport modes in former glacier systems (Figure 4). Recent studies have shown that glacial transport systems are more complex than envisaged in Boulton's original classification scheme. First, the associations between supraglacial and passive transport, on the one hand, and subglacial and active transport on the other, does not apply in all cases. On debris-covered glaciers, for example, boulders can grind against each other as they adjust to melting of the underlying ice, and smaller clasts can undergo significant wear during repeated gravitational reworking (Benn and Evans, 1998). Thus, edge-rounded debris does not necessarily imply subglacial transport. Second, the active-passive dichotomy does not encompass all possible modes of transport. For example, Spedding (2000) and Spedding and Evans (2002) used clast form analysis to show that glaciofluvial processes can transport large amounts of sediment through glaciers. The presence of glaciofluvially transported clasts may go undetected if data are analyzed using methods designed to distinguish actively and passively transported debris (see Benn, 2004).

Conclusion

These complications show that uncritical application of clast form analysis can lead to misleading conclusions. With care,

however, subtle differences in clast morphology can be used to reconstruct many aspects of former glacier systems. The key is a flexible approach to research design guided by a thorough knowledge of glacial and extraglacial sediment transport systems. Once attuned to the language of shape, roundness, and texture, you will truly believe a stone can speak.

Glaciofluvial Landforms of Deposition

Introduction: Glaciofluvial Systems

Glaciofluvial landforms are created by glacial meltwater processes, either upon, within, or beneath glaciers and beyond glacial margins. Glaciofluvial landforms can therefore be recognized in both present and past landscapes of alpine and continental glaciation.

Glaciofluvial systems exhibit a distinct magnitude and frequency regime, which contrasts with nonglacially influenced fluvial systems. Flow magnitudes within glaciofluvial systems fluctuate diurnally with snow and ice melt, seasonally with glacial ice ablation and snowmelt, episodically with glacial advances and recessions, and also by the release of stored meltwater. Glacier regime and stability are therefore crucial controlling factors in the glaciofluvial system. Distinction of glaciofluvial systems by climatic zones is perhaps inappropriate, however, because although glaciofluvial landforms are produced at different rates in polar, arctic, and alpine environments, the resultant landform morphology is often similar (Fitzsimons, 2003).

Glacial meltwater can route supraglacially, englacially, and subglacially before exiting from an ice margin into a proglacial zone (Figure 1). Routes depend upon water source, volume and release rate, and any preexisting supraglacial channels, crevasses, englacial passages, or subglacial cavities. Proglacial meltwater tends to follow preexisting topography although frequent channel avulsions occur due to glacier margin fluctuations and internal system adjustments of braided river systems. In the case of an exceptionally high-magnitude glaciofluvial flood, or 'jökulhlaup,' preexisting glacier margin topography and any proglacial river courses can be of little consequence to the route of meltwater (e.g., Russell and Knudsen, 1999). Glaciofluvial landforms can be produced within a range of unusual depositional environments such as glacier ice-walled tunnels or conduits, crevasses or fractures, and other ice-contact positions (Figure 1).

Besides meltwater, sediment flux is very important for determining glaciofluvial landform type. Sediment availability tends to be very high in glacial regions due to high erosion rates, and particularly during episodes of glacial retreat. Glaciofluvial sediment can be derived from valley walls, bedrock, and substrate erosion. Sediment flux affects flow rheology or flow behavior and can modify a flood hydrograph (e.g., Rushmer, 2006). For example, during a high-magnitude flood, sediment supply is likely to become exhausted, resulting in the development of a positive hysteresis loop (e.g., Old and Lawler, 2005) as well as pulses or 'slugs' of sediment-charged meltwater (e.g., Carrivick et al., 2004a,b). High-magnitude glaciofluvial flows can approach a hyperconcentrated state, with a greater tendency for upper flow regime bedform formation.

Owing to the range of scales at which glaciofluvial landforms exist, it is difficult to distinguish glaciofluvial landforms

of deposition from nonglaciofluvial landforms on the basis of morphology alone. It is therefore usually necessary to examine the sedimentary character of glaciofluvial landforms of deposition to identify diagnostic features. For example, ice-proximal glaciofluvial sediment is typically coarse grained, exhibits relatively poor sorting, and features abrupt changes in lithofacies. However, glaciofluvial landforms formed in an ice-contact situation will, with subsequent loss of ice support, feature sedimentary structures that are indicative of postdepositional modification, that is, shearing, faulting, slumping, and subsidence. Ice-contact glaciofluvial landforms may also be compressed and overridden by advancing glacier ice, producing characteristic reverse faulting and folding. Finally, it must also be considered that many glaciofluvial landforms can become reworked or modified by several events and processes. For example, depositional bars can become dissected by subsequent erosion, and bedrock or alluvial channels can become infilled.

Glaciofluvial Landforms of Deposition

Glaciofluvial processes produce a wide range of landforms that are here classified by location of formation, that is, proglacial or ice contact, and geometric scale (Table 1). The geometric scale of glaciofluvial landforms is determined by the size of the channel in which they are situated. This dependence on scale as well as position contrasts with standard fluvial bedform classification schemes (e.g., Leeder, 1999) that imply the action of depositional processes over relatively long periods of time. Proglacial landforms of deposition include outwash plains or 'sandur,' and also a series of bedforms that are found within channels on these sandur. Similar bedforms can also form in proglacial bedrock channels. Ice-contact glaciofluvial landforms of deposition include kames and eskers.

Macroscale glaciofluvial landforms are a cumulative result of numerous depositional events. They span kilometers in planform and include sandur and valley-fill deposits. Meso-scale landforms include bar and bedforms of several hundred meters in plan-form geometry, such as bars and dunes, and tend to be dependent upon reach-scale equilibrium sediment transport. Microscale landforms include ripples; they are generally products of transient hydraulics, and of a planform of the order of one to a few tens of meters.

Proglacial Glaciofluvial Landforms of Deposition

Sandar

The Icelandic term 'sandur' (*singular*) is synonymous with a braided proglacial outwash plain. Southern Iceland is the type-site for extensive outwash plains or 'sandur' (*plural*) such as Skeiðarársandur (Figure 2). Sandur character, in terms of geomorphology and sedimentology, is indicative of meltwater

Figure 1 Conceptual diagram of the glaciofluvial system. Note: Not all glaciofluvial processes and landforms are depicted.

Table 1 Glaciofluvial landforms of deposition, in relation to situation and spatial scale

Categories of landforms are italicized.

regimes dominated by either normal ablation-controlled flows, rainfall floods, or glacial outburst floods, ‘jökulhlaups’ (e.g., Carrivick and Rushmer, 2009; Marren, 2005; Russell et al., 2006, 2009; Sambrook-Smith, 2000). Jökulhlaups can be generated either by the release of stored meltwater or by the direct melting of ice and snowfields by subglacial geothermal or volcanic activity. Most sandar are a product of a highly variable discharge regime within a relatively sediment-rich environment dominated by fluvial bedload transport. Consequently, sandar support braided river systems with highly erodible bed and bank materials.

Terraces are a characteristic of many proglacial fluvial systems, including sandar. Terraces constitute abandoned fluvial surfaces that have been formed by incision from more recent flows. Stacks or flights of terraces therefore preserve a record of successive depositional and erosional episodes, which can be due to a change in external forcing such as climate, base level, discharge regime, or glacier snout advance/recession, for example. A single erosional event within a fluvial system may generate a ‘complex response’ within the downstream channel consisting of multiple cycles of deposition and erosion resulting in the formation of multiple terraces (Schumm, 1973).

Sandar are composed of a number of glaciofluvial bar and bed forms. Although unconfined sandar are dominated by aggradation, their detailed surface topography and subsurface sedimentary architecture consist of both erosional and depositional forms. Erosional forms are the product of ‘intrinsic’ processes such as channel confluence scour, bedform migration, and waning flow stage incision or ‘extrinsic’ external factors such as glacier margin fluctuations or base-level change. By contrast, topographically confined sandar are characterized by a greater interaction of flow with the surrounding bedrock topography and a relatively higher and more rapidly varying river level (e.g., Glasser et al., 2009; Russell et al., 2009). It is possible that a large range of both erosional and depositional landforms can occur upon confined sandar (Carrivick, 2007a,b).

Unconfined sandar

Unconfined sandar occur in coastal or piedmont locations, where glaciofluvial sediment aggrades freely in a distributary manner in the relative absence of lateral topographic controls. Frequent overbank deposition, continuous scour and fill, and persistent bar modification produce a continuously

Figure 2 Two examples of large sandar in Iceland. Orientation and limits of photograph of Skaftafellsjökull is indicated by arrow and dashed lines. Photo credit: Prof. Fiona Tweed.

evolving surface in the case of sandar produced by ‘normal’ ablation-dominated meltwater. Sandar dominated by episodic high-magnitude meltwater discharges, such as jökulhlaups, will contain numerous terraces and paleo-bar surfaces, as well as sediments characterized by lenticular and tabular bedsets, all associated with deposition from turbulent, transcritical-supercritical flow (Duller et al., 2008). Bedforms and bars on unconfined sandar vary in size, from meters to hundreds of meters.

Sandar are typically concave in long profile. Marked downstream reduction in sandur gradient combined with progressive increase in channel system width results in a rapid downstream decrease in flow energy. As a result, major proximal–distal changes in grain size and depositional style can be detected on most unconfined sandar (Boothroyd and Nummedal, 1978). Proximal sandar surface morphology commonly comprises high-relief amplitude boulder bars incised by large channels. Ice-contact bar morphology is often controlled by meltwater vent or conduit mouth location and geometry, with bars radiating from an outlet channel or artesian vent. Ice-block obstacle marks and kettle holes also tend to be the largest and most prevalent near a glacier margin. Proximal grain size and lithofacies variations are highly variable. However, with increasing distance downsandur, large-scale bar and channel systems give way to a more complex braid pattern. Generally, clast sizes, clast size variation, and lithofacies variation also decrease downsandur, and clast roundness increases. In Alpine environments, nonglacial sources of water via tributaries from the nonglaciated parts of the catchment dampen discharge fluctuations with increasing distance downsandur.

Confined sandar

Meltwater flows constrained by areas of high relief are constrained by topography and thus are characterized by flows with greater depths and stream powers (Baker and Costa, 1987). This is partly because at high discharges, valley walls form resistant channel boundaries, and downstream constrictions in valley cross-profile may result in temporary backwater zones (Russell and Knudsen, 1999; Russell et al., 2009). Within a jökulhlaup-dominated system, the sedimentary infill of a given reach may be entirely depositional, or may contain both erosional and depositional forms, depending upon the ratio of flood magnitude to local channel gradient and geometry (e.g., Carrivick et al., 2004a,b). Such thick accumulations of sediment can be termed valley-confined sandar, valley-fill sediments (e.g., Church, 1978), or valley train deposits (Figure 3). Giant fluvial bedforms, particularly giant gravel bars, are common in confined sandar.

Many valley-confined sandar are dominated by a proximal flow expansion from either conduits or narrower bedrock-controlled feeder channels (Baker and Kochel, 1988). In medial channel zones, all other depositions tend to be focused at valley margins as longitudinal bars, point bars, or as pendant bars (Baker and Kochel, 1988). Vigorous lateral flow separation occurs within alcoves or reentrants in bedrock valley sides, generating eddy bars. In distal zones, deposits may comprise slackwater sediments emplaced within tributary valley mouths (e.g., Glasser et al., 2009). Main channel distal deposits can result from bedrock topographic constrictions that induce localized backwater ponding. While down-slope reductions in clast size, clast size variation, and lithofacies

Figure 3 Valley-fill sediments, 2 km wide, at Kverkfjöll, Iceland. Note isolated fluvially transported boulders. Thick accumulations of glaciofluvial sediment can exist in predominantly bedrock channels where local channel gradient rapidly decreases or where a valley cross-section widens.

variation are common to all sandar, greater spatial variation of depositional style can be expected within valley-confined sandar (Figure 4).

Giant fluvial bedforms

Glaciofluvial systems provide the best examples of giant fluvial bedforms such as dunes, antidunes, ice-block obstacle marks, and chute and pool complexes. As the morphology of giant bedforms may be confused with glaciofluvial bars, glaciolacustrine deltas, and kame terraces deposited by more frequent low-magnitude flows, great care must be taken when describing and interpreting both surface and subsurface sediments. Therefore, a holistic assessment including location, situation, scale, and sedimentology is emphasized below.

Gravel dunes

Giant gravel dunes are perhaps the most distinctive but least common bedforms attributed to glacial outburst floods. Giant gravel dunes are also referred to in the literature as giant dunes, gravel ripples, giant current ripples, and megaripples. Gravel dunes are sparsely reported in the literature due to comparative rarity of occurrence and generic confusion with antidunes and classes of gravel bars (Carling, 1999). Furthermore, since flow must be hydraulically smooth for the generation of ripples and hydraulically smooth flow is not associated with mobile gravel, it is most likely that observations of gravel ripples are actually incipient or transient dunes (Carling, 1999; Carling et al., 2002). Giant gravel dunes are controlled by flow depth and the size of particles available for transport and are thought to develop within subcritical flows, at Froude numbers of up to 0.75, although due to lag effects, transitional bedforms have been recorded for Froude numbers near the supercritical flow value of 1 (Carling, 1996, 1999).

Giant gravel dunes were first identified in association with the drainage of Lake Missoula (Baker and Bunker, 1985), and particularly within zones of flow expansion. Over 100 'trains' were identified with individual dunes of heights up to 15 m and wavelengths up to 150 m. Since then, there have been reports of giant gravel dunes in the Altai Mountains of Siberia

Figure 4 Confined outwash plain at (a) the Franz Josef glacier and (b) the Tasman valley, both New Zealand. The contrast between the boulder bar and the fine gravel bar in the foreground of (a) demonstrates considerable spatial flow variability. Both outwash plains are confined by steep valley walls and are of a gradual concave long profile. Photo credit: Dr. E. Lucy Rushmer.

with crests rising up to 10 m above their troughs with a wavelength of 50–150 m (Baker et al., 1993).

Besides an obvious flow-transverse undulating morphology, the sedimentology of giant gravel dunes is remarkably consistent between sites. They comprise coarse gravel-sized material that forms large foresets, with cross-strata frequently occurring at angles of up to 35° (Carling, 1996, 1999). Gravel foresets separated by reactivation surfaces are indicative of repeated high discharges (Russell and Marren, 1999). Large-scale gravel foresets record progressive downstream bedform migration by lee-side 'avalanche' processes (Carling et al., 2002). Giant gravel dunes are thought to be initiated by the migration of gravel sheets at high flow stage.

Gravel antidunes

Antidune bedforms develop in transitional-supercritical flows (Froude number ~ 1) in phase with stationary or upstream-migrating surface water waves. Antidunes are products of upstream bedform migration with crests typically orientated transverse to flow. Upstream dipping or 'backset' strata record progressive accretion of the bedform stoss side simultaneously with lee-side scour. Antidunes may also be completely erosional in nature developed within erodible bed materials. Antidune backsets typically dip upstream at a shallow angle ($\sim 2\text{--}3^\circ$). Development of antidunes within gravel (e.g., Duller et al., 2008) requires relatively shallow, supercritical flows with sufficient power and coarse-grained sediment availability. Preservation of gravel antidunes requires either sufficiently rapid flow stage reduction so as to prevent bed reworking or high-enough bed aggradation rates to allow bedform preservation at depth.

Ice-block obstacle marks

Ice blocks can become detached from a glacier snout due to differential ablation or mechanical fracturing. Hollows or pits within a sandar surface formed by the meltout of these ice blocks while they are held within glaciofluvial sediments are called kettle holes (e.g., Kjaer et al., 2004). Ice blocks can also be transported within high-magnitude floods from glaciers; jökulhlaups (Burke et al., 2010; Fay, 2002; Russell, 1993). Subsequent fluvial scour and deposition around an ice block can produce ice-block obstacle marks (e.g., Russell, 1993). Ice-block obstacle marks can be distinguished from kettle holes by a number of geomorphological and sedimentological features (Fay, 2002; Figure 5). For example, ice-block obstacle marks

Figure 5 Development of antidune stoss-side strata within an ice-block obstacle mark. Redrawn from Fay H (2002) Formation of ice-block obstacle marks during the November 1996 glacier-outburst flood (jökulhlaup), Skeiðarársandur, southern Iceland. *Special Publication of the International Association of Sedimentologists* 32: 85–97.

tend to occur in association with depositional bars and may exhibit a boulder-like downstream fining in clast size (Fay, 2002). In contrast, buried stagnant glacial ice generally leads to bigger and spatially unsorted kettle holes. In terms of sedimentology, ice-block obstacle marks can feature distinctive antidune stoss-side strata, indicating localized supercritical flow around an ice block (Burke et al., 2010; Maizels, 1995, 1997). They commonly have aggradational obstacle shadows consisting of crudely bedded, matrix-supported, boulder gravel and stoss-side stratified open-work cobbles (Fay, 2002). The presence of well-sorted, stratified, and clast-supported gravel further suggests turbulent fluidal flow (Maizels, 1995, 1997).

Proglacial subaerial mesoforms

Channel macroforms or channel scale bars within subaerial environments can be classified into braided river bars, expansion bars, eddy bars, and pendant bars (Church and Gilbert, 1975). These forms are classified according to distinct processes and mechanisms operating at a channel scale within rivers. Braided river bars can be produced from a continuum of flow magnitudes and regimes. Expansion, eddy, and pendant bars tend to be associated with high-magnitude discharges, and specifically with a hydraulic jump, from subcritical to supercritical flow and the subsequent development of a fluvial shear zone.

Bars

Braided rivers have a multithreaded planform comprising many confluences and diffluences (Miall, 1977). Braid bars and channels can be classified as a hierarchy depending upon their relative size, and three orders of braiding can be seen in proglacial rivers with constant discharge (Williams and Rust, 1969; Figure 6). First-order braid bars are those largest bars that are separated by major channels. First-order bars are made up of a series of smaller, second-order braid bars, which are separated by smaller channels. Third-order braid bars are contained within second-order bars. The complexity of braid pattern is however, strongly stage-dependent, with rivers losing their braided character during peak flood conditions. Mid-channel or central bars, which include crescentic, longitudinal, and transverse bars, bank-attached, point, or unit bars, and larger composite forms known as compound bars or braid bar complexes, have been described in braided river systems on a range of scales ranging from meters to kilometers. All bars are subject to constant dissection via splays and chutes

Figure 6 Development of chute channels on a bar upon a small confined outwash plain in New Zealand. Chute channels and bar dissection are products of fluctuating meltwater discharge and sediment flux. Photo credit: Dr. E. Lucy Rushmer.

(Figures 6 and 7), remobilization and migration (Miall, 1977, 1983). Only the largest bar forms produced by the most powerful flow events such as jökulhlaups may become stable over periods of years.

Bar formation can occur by deposition of material or by erosional dissection or preexisting topographic highs (Maizels, 1995). Bar growth occurs when initially small irregularities in a channel are amplified by deposition, creating conditions favorable for continued accumulation of sediment. Erosion and deposition can occur simultaneously, with sediment being gained and lost from different parts of the same bar.

Distinguishing between bars and islands in braided rivers is obviously problematic (Figure 8), as is a clear understanding of the influence of flow stage on braided river classification. For example, it is typically difficult to decide which channel segments should be used to define channel sinuosity and which bars should be used to define channel splitting (Figure 8). Besides river discharge regime, the volume and character of glaciofluvial sediment is a key factor in controlling braiding (Church and Gilbert, 1975).

Expansion bars

Expansion bars are associated with deposition downstream of zones of rapid flow deceleration, such as hydraulic jumps generated at the junction between steep, confined reaches and wide- and low-gradient reaches (Baker, 1984; Figure 9). Expansion bars initiated at flood peak become progressively modified as stage recedes (Church and Jones, 1982) and also during subsequent flow events. Waning stage flows may incise expansion bars, commonly forcing a terraced or channeled surface and a fan-like plan, although incision may be inhibited in fluvial systems dominated by boulder-sized sediment. Identification of expansion bars may be aided by bar-surface cobble and boulder lags, which represent winnowing of fine-grained

clasts during receding flows (e.g., Carrivick et al., 2004a,b). Sediment clast sizes typically show a marked decrease in a downstream direction upon expansion bars and also units that become progressively finer upward.

Figure 8 An example of a glaciofluvial braided river comprised of numerous stream threads and constantly altering sand and gravel bars. The 2-km-wide active channel develops a ceaseless pattern of deposition and remobilization.

Dashed arrows indicate flow direction, and major slackwater zones are indicated by white arrows.

Eddy bars

Eddy bar sediments are derived from two different sources; namely from tributary flow and from marginal channel flow (Figure 10(a)). Eddies result between zones of higher and lower velocity flow and promote deposition due to abruptly decreased sediment transport capacity (O'Connor, 1993).

Eddy bars can contain a wide variety of sediment sizes and structures, including poorly sorted, commonly cross-stratified boulder gravel and cross-stratified graded gravel (Church and Jones, 1982; Figure 10(b)). Typically, foresets dip away from the main flow direction, containing well-sorted subrounded boulders and cobbles with an open framework structure (Miall, 1983). Thus, varying directions of transport are distinguished, whereas in a pendant or expansion bar, flow is more unidirectional. Smaller foresets comprise granules and pebbles dipping locally upstream, thus reflecting swirling eddies. Eddy bars at tributary mouths tend to grade upstream into slackwater deposits (Figure 10(b)). Deposition during multiple events may result in interfingering of graded sand-silt units with laminated silt units (Figure 10(b)).

Pendant bars

Pendant bars are narrow, sharp-crested, streamlined landforms of sand and gravel-sized clasts, which are deposited

Figure 11 Schematic development and characteristics of pendant bars (a). Redrawn from Baker VR (1978) Large-scale erosional and depositional features of the channelled scabland. Washington, DC: National Aeronautical Space Administration. Example of a pendant bar in west Greenland (b); note persons for scale.

immediately downstream of obstacles within a main flow path (Figure 11(a) and 11(b); Miall, 1983; Russell and Marren, 1998). Pendant bars up to 2 km long and 30 m high have been identified in steep channels of uniform gradient within the Missoula flood landscape (Baker, 1978, 1984; Baker and Bunker, 1985; Baker and Kochel, 1988). Deposits in the lee of large bedrock obstacles can be regarded also as pendant bars (Figure 11(a) and 11(b)). Pendant bars are therefore commonly associated with proximal and lateral hollows formed by intense and localized scour. Relative flow depth around or over the obstacle will determine the exact interaction between hydraulics and sediment. If an obstacle is completely submerged at high flow depth, pendant bars may develop as products of a localized hydraulic jump, as flow accelerates over the obstacle (Figure 11(a)). The internal structure of pendant bars can consist of simple large-scale gravel foresets or massive matrix-supported gravel. In the Altai, coarse-grained pendant bar sediments typically consist of high-amplitude gravel foresets interpreted as the product of bar deposition by deep flows (Baker et al., 1993). The predominance of large foresets in the bars suggests growth by downstream progradation, rather than by vertical accretion.

Ice-Contact Glaciofluvial Landforms of Deposition

Glaciofluvial deposition in supraglacial, englacial, subglacial, and proglacial environments can produce ice-contact landforms. Ice-contact depositional landforms are usually classified as linear or nonlinear features depending on the nature and degree of glacier control on meltwater flow pathways. Ice-contact landforms experience postdepositional modification

to varying degrees due to loss of support upon ice melt, or compression by glacier ice advance, or overriding.

Linear features

Kame terraces and glaciofluvial eskers are deposited directly in contact with glacier margins and ice-conduit walls, respectively. Kame terrace and esker morphology is a direct reflection of the linear nature of their respective ice contacts.

Kame terraces

Kame terraces are generally discontinuous and often pitted benches deposited by rivers flowing between a valley side and an ice margin (Figure 1). They are usually located on the distal slopes of recessional marginal 'moraine' ridges and developed during deglaciation, probably due to the interaction of active ice lobes (surges) and masses of dead ice that persisted beyond the ice margin (Bitinas, 2011). Kame terraces, therefore, frequently occur in stacks or flights on either side of a valley. They may not be altitudinally matched (paired), nor have similar gradients, but do tend to have gently sloping surfaces which reflect the gradient of the former ice margin (Figure 12(a)). Parallel kame terraces on a single valley side typically represent successive stages in the lowering of a glacier surface

Figure 12 Parallel kame terraces with gently sloping surfaces representing successive downwasting of the glacier surface (a), and are composed of glaciofluvial sands and gravels (b).

(Figure 12(a)). Kame terraces are predominantly composed of sands and gravels (Figure 12(b)), but can also contain glaciolacustrine deposits from meltwater ponds.

Eskers

Glaciofluvial eskers are named after the Irish 'eiscir,' which means ridge, and are known as 'osar' in Scandinavia (Benn and Evans, 2010). Eskers have many possible origins including sub- and englacial conduit deposits (Figure 1), fracture fills, ice-walled open-roofed channels, and subaqueous outwash fans (Brennand, 2000; Warren and Ashley, 1994). They can be formed by deposition of sediments from 'normal' ablation-controlled meltwater, or during episodic high-magnitude discharges, such as jökulhlaups. Esker ridges often emerge from chaotic downwasting surfaces of ice-cored outwash (e.g., Boulton et al., 2007; Burke et al., 2008; Russell et al., 2006) and can show evidence of continuous deposition over hundreds of kilometers. Such distances might indicate regional ice-sheet stagnation (Brennand, 2000) or a strong coupling of subglacial pathways with groundwater catchments, most likely during deglaciation (Boulton et al., 2007). Segments of an esker may be deposited time-transgressively during glacier retreat (Warren and Ashley, 1994). Hooke et al. (2007) reported that segments of an esker increase in size down-ice as a product of melt rates exceeding tunnel closure rates by an increasing amount toward the ice margin, leading to a reduction in water flow velocity and increased deposition of sediments. Conduit-fill eskers can be found in isolation (Figure 13) or within interconnected anastomosing networks (Figure 14) whose routeways are determined by ice-sheet surface morphology and subglacial topography interactions. Glaciofluvial esker segments can terminate in subaerial or subaqueous outwash fans to form esker beads. A 'till esker' has been identified by Evans et al. (2010) at Sandfellsjökull in southern Iceland and attributed to squeezing of a dilatant till into an elongated cavity or R-channel after meltwater evacuation. This deposit is indirectly linked to glacial meltwater, which must have generated appropriate conditions for nonfluvial emplacement of till. Eskers tend to display considerable downstream variation in morphology,

Figure 13 Example of a ~3 km esker in northern Sweden.

Figure 14 Schematic diagram of the common spatial relationship between eskers, sandar, moraine, and ice-contact fans. Redrawn from Price RJ (1969) Moraines, sandar, kames and eskers near Breiðamerkjökull, Iceland. *Transactions of the Institute of British Geographers* 46: 17–43.

with localized gaps and enlargements, which reflect deposition within expansive sub- and englacial cavities and zones of non-deposition, respectively. Eskers can be composed of a wide range of facies, including silts, sands, gravels, boulders, and matrix-supported diamictos. Englacial esker sediments experience great postdepositional modification during meltout, resulting in less well-defined ridge morphology. Removal of ice support from sub- and englacial eskers produces slumping characterized by normal faults.

Fluvial processes within conduits differ from those in sub-aerial environments in a number of ways. Meltwater within conduits flows down a hydraulic gradient controlled by glacier surface slope, allowing pressurized water to flow up-hill (Röthlisberger and Lang, 1987; Shreve, 1972). Meltwater pressure and velocity within conduits are highly variable due to temporal and spatial variations in meltwater discharge and conduit size. Conduit diameter is a function of the balance between meltwater-driven melting and closure due to plastic deformation of glacier ice. Maximum flow velocities within eskers are thought to be higher than within subaerial fluvial systems due to low conduit roughness.

Conduit eskers are characterized by their distinctive large-scale sedimentary architecture. In cross-section, the characteristic arched or pseudo-anticlinal structure of eskers is believed to develop when deposition is dominated by large-scale vortices, which sweep sediment from the flanks into the middle of the esker ridge (Brennand, 2000). Esker sediments also may fine laterally, away from ridge crests, usually with a transition from large-scale cross-bedded gravel and boulders in the esker core to horizontally bedded sand and laminated silt at the margins. These sedimentary sequences are thought to represent conditions where the conduit is expanding via ice wall melting and/or mechanical erosion. Where conduit geometry is irregular, channel macroforms are deposited at flow expansions (Brennand, 2000; Burke et al., 2008). Macroforms, hundreds of meters in length and tens of meters in thickness, display large up-stream dipping stoss sides and distal foreset beds. Macroforms can be deposited within single events, such as jökulhlaups (Burke et al., 2008, 2010), or can be deposited by repeated events. Large-scale gravel dunes and gravel sheets are commonly superimposed upon esker macroforms. Although esker facies and grain sizes include those commonly found within all glaciofluvial settings, esker core sediments do contain a greater occurrence of matrix-supported gravel and boulders,

which reflects rapid deposition from highly sediment-charged flows (Brennand, 1994, 2000).

Nonlinear features

Nonlinear ice-contact glaciofluvial features include subaerial outwash fans, kames, and hummocky terrain. These landforms are products of deposition at ice margins or within subglacial cavities.

Subaerial outwash fans

Ice-contact outwash fans are fed by either sub-, en-, or supra-glacial meltwater systems, and may therefore be associated with esker ridges (Figure 14). They are suggested to be an end member of a continuum of landforms (e.g., Pisanska-Jamroz, 2006). Outwash fans range from decimeter to kilometer in scale and are usually composite cone-shaped landforms created by aggradation of material deposited from a range of flow events of varying magnitude and frequency. Additionally, outwash fans are created during glacier surges or during jökulhlaups (Russell and Knudsen, 2002; Russell et al., 2001). Outwash fans are a cone of aggradation (Figure 14), radiating from an apex at an ice-marginal meltwater portal. Outwash fans in close proximity to each other coalesce (Figures 14 and 15) to form large glaciofluvial ‘end’ moraine complexes such as the Salpausselkä ridges in southern Finland. Outwash fans have steeper slopes than sandar, which they grade into (Figure 15). Steep fan gradients encourage the

Figure 15 An ice-contact subaerial outwash fan at Skeiðarárjökull, Iceland.

Figure 16 Example of kames, or hummocky meltout topography.

development of supercritical flows generating planar bed conditions and localized antidunes. Outwash fan sediments typically comprise fan surface parallel bedding and localized low-angle backsets (Russell and Knudsen, 1999, 2002).

Kames

The Scottish words ‘cam’ or ‘kaim,’ which mean ‘sinuous steep-sided mound,’ are the origins of the term kame (Benn and Evans, 2010). The term kame refers to a suite of steep-sided mounds that are usually deposited supraglacially or at an ice margin. An example is moulin deposits. Kame and kettle topography (Figure 16) is a zone of ridges and mounds, or ‘kames,’ between kettle holes. While kettle holes are products of the melting of buried glacial ice, kame ridges and mounds are glaciofluvial deposits. Kame deposits can be disarranged or with some alignment, reflecting former glaciofluvial routes and characteristics (Roberts et al., 2001). Although kames comprise the complete spectrum of glaciofluvial deposits, they commonly display signs of postdepositional modification due to the removal of ice support comprising normal faulting and sagging/collapse. Thus, kames, like eskers, can exhibit complexity and interconnectivity on both temporal and spatial scales; that is, in both formation and preservation. Livingstone et al. (2010) have recently described these characteristics for the Brampton kame belt.

Links to Other Systems

Glaciofluvial systems are driven by fluctuations in glacier mass balance and to a lesser extent by rainfall–runoff events. Glacial erosion is a major supplier of glaciofluvial material, and finer-grained sediment is often sourced from aeolian action, which is enhanced by strong thermal gradients in glacial terrain. Landforms of glaciofluvial deposition are influenced by local topography, geology, and situation. Glaciofluvial systems can be directly coupled to glaciolacustrine and glacimarine environments, by conduits within tidewater glaciers, for example. Indirect coupling of glaciofluvial and glaciolacustrine or glaci-marine systems can occur via delta-top environments, such as fjord-head sandar and large coastal sandur–delta complexes, such as Skeiðarársandur in southern Iceland.

Conclusion

Glaciofluvial processes are effective agents of landscape change, eroding, transporting, and depositing large amounts of sediment at a wide range of spatial scales. Macroscale landforms are composite landforms, formed cumulatively by a range of meltwater discharges and sediment flux regimes. Macroforms can, in exceptional cases, be produced by episodic high meltwater discharge, such as from glacier surges, or from glacial outburst floods or ‘jökulhlaups.’ Mesoscale landforms include bedforms of several hundred meters in plan-form geometry, such as dunes and bars, and tend to be dependent upon reach-scale equilibrium sediment transport. Microscale landforms include ripples, are generally products of transient hydraulics, and are of a plan-form of the order of one to a few tens of meters. Glaciofluvial processes are controlled by glacier mass balance and resultant meltwater discharge, and are therefore intimately linked to glacier fluctuations. Glaciofluvial systems transfer vast amounts of sediment, to other fluvial, lacustrine, and marine environments. Sediment is most abundant proximal to active ice margins. Glaciofluvial landforms of deposition can be categorized as either proglacial or ice-contact landforms. On the basis of morphology alone, both types of landforms are difficult to unequivocally identify, without recourse to sedimentary character, depositional setting, and geometric scale. Additionally, ice-contact landforms will inevitably feature secondary deformation as ice support is lost due to ice mass melting. However, recognition of glaciofluvial landforms can permit reconstruction of glacial ‘plumbing’ systems and can imply glacier behavior from meltwater discharge magnitude–frequency regimes. Reconstructions of past glaciofluvial events in space and time, and hence of glacial activity, are important for understanding glacial chronology and glacial responses to, for example, climate change.

Glaciogenic Lithofacies

N Eyles and M Lazorek, University of Toronto, Toronto, ON, Canada

© 2013 Elsevier B.V. All rights reserved.

The Meaning of Facies

The term glaciogenic refers to any sediment or landform that results from glacial action. In the main, glaciogenic sediment is produced directly by erosion and comminution at the base of glaciers and ice sheets and redistributed by other processes. The word facies means 'appearance of' (hence 'face'). Lithofacies are simply different types of clastic or chemical sediments (and their lithified rock equivalents) produced by gravity, water, ice, or wind in sedimentary environments. Sediments are readily classified informally into facies based simply on color, texture, lithology of clastic particles, internal structure, thickness and geometry, presence or absence of body and trace fossils, and any postdepositional structures (e.g., reddish, fossiliferous, pebbly quartz-rich sandstone with burrows). There are several formal classifications of sedimentary lithofacies (Eyles et al., 1983; Ghilardo, 1992; Walker, 1992). A widely used practice is to study lithofacies accumulating in the present day and use these as keys to interpret ancient deposits and their formative processes. Unfortunately, few sedimentary environments are typified by a single diagnostic lithofacies because most environments are spatially complex, involving the interaction of many different processes. An exception is the environment where large storm waves create distinct hummocky bedforms in shallow water (producing a distinctive hummocky and swaley cross-stratified sand facies). The latter is referred to as a so-called universal facies type because its origin is unique to a particular setting (i.e., wave-dominated shallow water). Another example is that of a graded turbidite bed deposited by turbidity currents flowing downslope under water. So-called common facies types, on the other hand, are produced in many environments (eolian, deep marine, fluvial, etc.) and are not uniquely diagnostic of any one depositional setting (e.g., rippled cross-laminated sands).

The Complex Glacial Environment

Consider the wide range of environments found around glaciers (Figures 1(a), 1(b), and 2). Meltwater emerges from under the ice as large rivers that are often ponded in front of (or even under) glaciers to form lakes in which large fans and deltas are built. Seasonal and long-term variations in the position of the ice front give rise to complex diachronous (time-transgressive) patterns of sedimentation and partial destruction, and reworking of glacial facies either by melt streams or bulldozing by the ice front. In the absence of vegetation and the presence of strong downglacier (katabatic) winds, eolian transport and deposition of fine sediment are important. Steep slopes and melting ice result in mass movement processes. In marine environments where glacial sediment was deposited under water, crustal rebound may lift sedimentary successions either above water or into energetic shallow waters where they will be reworked and redeposited.

Typical glaciogenic sediment is poorly sorted and uniquely fingerprinted by the presence of striated and glacially shaped pebbles or boulders. The greatest yields of such sediment (mostly in the form of silt, so-called rock flour) are from temperate wet-based valley glaciers that are able to slide rapidly across their relatively steep beds (e.g., Hooke and Elverhoi, 1996). These glaciers are capable of eroding their beds to form deep basins often enclosed by rock bars. This creates a typical up-and-down and locally overdeepened long profile (thalweg) in glaciated valleys; glaciated basins often exhibit parts that have been eroded well below sea level (e.g., Great Lake basins in North America). The lower seaward end of glaciated valleys forms narrow, steep-walled, and very deep troughs or fjords.

Glaciers in areas of permafrost (dry-based polar glaciers) are frozen to their beds and move slowly by internal creep and so do not generate a thick depositional record. Ice streams form where parts of polar ice sheets can slip on wet sediment (Bennett, 2003). Subpolar glaciers share characteristics of both wet- and dry-based glaciers. While useful in terms of understanding modern glacial processes and deposits, a thermal regime cannot easily be inferred from ancient glacial lithofacies. A polar thermal regime is transitory; at the end of any one glaciation, dry-based glaciers eventually warm and melt. Polar conditions predominate today in Antarctica but ancient deposits preserved along the continental margin record sediment delivered by wet-based glaciers (e.g., Eyles et al., 2001).

Diamict Versus Till

Diamict (diamictite when a rock) is a nongenetic umbrella term for any poorly sorted deposit regardless of depositional environment (Figures 1(c), 1(d), and 3(a)). Man-made concrete is a diamictite. Sliding glaciers produce a wide range of diamicts that contain admixtures of most textural classes ranging from clay to large boulders. These diamict facies are specifically identified as till because they were deposited directly by ice. A till (tillite: rock) is a specific genetic term for a diamict deposited directly from ice either terrestrially on land or in the glaciomarine realm.

Diamicts form in a wide range of glacial and nonglacial environments such as on the slopes of volcanoes, under water, or on land where debris moves downslope as debris flows or in addition as a consequence of meteorite impact (Figure 3(a) and 3(b)). They are said to be a common facies (not universal facies; see above) because they have no unique environmental interpretation. They look very similar regardless of their origin. It is by the study of other facies with which they are conformably interbedded that valuable information regarding depositional setting is gained. Walther's law states that facies found in a continuous vertical sequence must have been spatially related at the time. If, on the other hand, facies are separated

Figure 1 (a) Many processes in areas of wet-based glaciation are dominated not by 'glacial' processes per se but by the activity of meltwater. Here is an extensive braided outwash plain in southern Alaska where meltwaters leaving the ice front have reworked almost all primary glacial sediment and landforms. (b) A calving tidewater ice margin (see [Figure 9](#)). (c) Diamict deposited by debris flow processes. (d) Subglacially deposited deformation till ([Figures 4](#) and [6](#)). (e) Diamict deposited underwater by downslope flow; note systematic coarsening of pebble sizes upward (known as inverse grading developed where debris flows become transitional to turbidites; [Figure 3\(b\)](#)). (f) Classic varves composed of couplets of summer deposited silt (white laminae) and dark winter mud. Numerous white-colored granules of silt (silt clasts) were brought in during summer underflows ([Figure 7](#)).

by disconformities or unconformity surfaces, then the facies above or below a diamict can provide little information. The application of Walther's law yields some indication of the overall depositional environment (whether it was deposited in deep or shallow water; or on a slope; or near a volcano or an impact crater; or onland, in a terrestrial setting, under a glacier perhaps?). A diamict conformably interbedded within undisturbed turbidites cannot be a till but is more reasonably interpreted as a debris flow since these are genetically related to turbidity currents. This sort of contextual analysis greatly constrains the possible origin of the diamict(ite).

Conceptually, till is deposited in three ways. Till accumulates by the passive meltout of englacial debris under stagnant dead ice (meltout till), by meltout of debris from flowing ice (akin to smearing peanut butter on toast: lodgement till) or by subglacial mixing of preexisting sediment (akin to smearing peanut butter on soft bread: deformation till; [Figure 4](#)). Most tills found in mid-latitude areas affected by Pleistocene ice sheets are probably deformation tills; subglacial shearing and mixing of preexisting sediment is the most efficient method of making, transporting, and depositing large quantities of till. Deformation till is commonly massive, rests on deformed

Figure 2 Principal glacial depositional systems associated with large ice sheets that reach sea level. Quaternary glaciations have left a very prominent glacial record on land but most sediment (perhaps as much as 90%) is deposited offshore on continental slopes. Such deposits dominate the record of older glaciations in Earth history because the terrestrial record is easily eroded.

substrate sediments, and usually includes rafts of undigested substrate sediment in its basal parts recording incomplete mixing. Some are held to exhibit lamination and banding similar to gneissic textures in high-grade metamorphic rocks subject to strong shearing. The same facies are produced by debris flows under water, however requiring care in interpretation and consideration of the wider depositional context. At modern glaciers flowing over stiff rock, lodgement till is more important. Meltout will be of local significance where evidence indicates that ice has stagnated and melted *in situ*.

There have been several techniques confidently proposed in the past as a Holy Grail for identifying subvarieties of till. Such methods center on samples examined in the laboratory and include geochemical and grain size characteristics, small-scale structures seen in thin sections, microsurface textures of quartz sand grains, or the orientation of clasts (clast fabric analysis). All of them ultimately proved simplistic because of overlapping properties. In reality, till is deposited by interactions of all the three processes identified above (indeed, processes may change through time at any one site) but one process will be dominant. Volumetrically, most till is

produced by subglacial deformation of other sediments as ice sheets grow and expand outward and cannibalize their own outwash deposits.

Glacial Depositional Systems: Facies Models and Facies Associations

Geologists recognize a wide range of different environments around and under the margins of glaciers, each one creating a distinct depositional system. These systems do not have sharp boundaries but are intimately linked as a consequence of sediment moving from one system to another (Walker, 1992). The system forms a characteristic deposit with a distinct morphology (e.g., a deltaic depositional system) and several recurring systems occur in glacial environments (Figure 2). Terms such as landsystem and landform/sediment association have also been used. One advantage of this approach is that in areas of modern-day and Pleistocene glaciation, it is possible to predict the types of facies found in the subsurface by simply identifying landform types typical of different systems.

Figure 3 (a) Diamicts form in a wide range of environments. Identifying diamicts deposited directly by glacier ice (till; e.g., [Figure 6](#)) requires analysis of associated facies. (b) Gravity-driven processes and their deposits.

In pre-Pleistocene rocks, however, this cannot be done, and interpretation is reliant on consideration of facies associations.

Facies associations are defined as distinct vertical successions of genetically related lithofacies ([Miall, 1997](#); [Walker, 1992](#)). As emphasized above, it is by recognizing these packages (rather than any one unique facies type) that ancient glacial settings can be recognized. A three-dimensional (3D) block diagram called a facies model is a useful tool for representing depositional systems and their constituent facies associations. These models provide a mental image that can embrace different data derived from studies of outcrops, subsurface drill core, or geophysical data (such as 3D seismic or ground-penetrating radar), and the study of processes and deposits in a controlled laboratory experiment. The model will vary from one particular case to another (such as tectonic setting), but it is a useful tool for distilling large amounts of data, for predicting subsurface conditions and for comparison with stratigraphic successions of unknown origin. Drawing a facies model forces consideration of the 3D distribution of facies.

For each depositional system (and thus facies model), a representative vertical profile can be made showing typical facies and the sedimentary evolution of the system through time ([Figure 5](#)). These profiles suffer from the obvious limitation of depicting 4D conditions in two dimensions, but the detailed assessment of facies in measured outcrops or drill core (called facies logging) is the essential starting point in any analysis. Simple lithofacies codes are available to aid labeling and identification and serve as a reminder of what to look for

in the field. Two-dimensional panels (say of cliff exposures) are very useful in showing lateral variability and 2D geometry of facies (such as those found in channels) and, increasingly, there is a move to consider the 3D architecture of deposits. Much progress has been made in this respect in fluvial, eolian, and deep marine environments (prompted by the search for hydrocarbons and reservoir analysis by petroleum geologists, and aided by geophysical techniques such as 3D seismic). The need to model the movement of groundwater through glacial sediments is a major stimulus ([Boyce and Eyles, 2000](#)).

Terrestrial Glacial Depositional Systems

Subglacial Depositional System

The terrestrial subglacial depositional system is composed of sediments deposited under the ice, and is typically dominated by sheet-like deposits of deformation till ([Figure 6](#)). These tills rest on eroded and deformed remnants of older preexisting sediment. These were glaciotectionized when ice advanced over the sediments and they were remobilized as till. A low-relief landform called a till plain (ground moraine of the older literature) is created. The most distinctive feature of a till plain are bedforms called flutes (long and thin) and drumlins (long and wider) elongated in the direction of ice flow. The origin of these is still contentious but they are increasingly being recognized as a product of either erosion of preexisting sediment (e.g., where they show cores of nontill sediment) or deformation and remobilization of deformation till ([Benn and](#)

Figure 4 Summary diagram of processes operating below ice of contrasting thermal regime. The generation and movement of till as a deforming layer (5) occurs below the outer margins of a wet-based ice sheet resting on sediment. Most modern glaciers are sliding on rock and are unrepresentative of Quaternary ice sheets.

Evans, 1998; Boulton, 1996; Hart, 1999). Fundamentally, a streamlined till plain is the 'soft bed' of the former glacier, in effect a giant slickenside surface such as along a fault plane veneered by ground-up rock (gouge). End moraines are ridges that form perpendicular to ice-flow direction and mark pauses in ice retreat, creating a ribbed appearance to the till plain. Moraines are built either by the extrusion of soft deforming till from under the ice margin or by bulldozing of sediment by a

readvancing ice front. The gravelly deposits of subglacial rivers are left as sinuous esker ridges (Brennand, 1994).

Till plains may be overlain by extensive spreads of gravelly outwash facies (e.g., Kjaer et al., 2004) and silty glaciolacustrine deposits left from ephemeral lakes ponded against the retreating ice margin. Glacial outwash deposits are dominated by poorly sorted, crudely bedded, sheet-like gravel facies deposited in shallow braided rivers. There is an absence of

Figure 5 Typical vertical profile showing facies types, paleocurrents (small circles with arrows), and amount of ice-rafted debris (IRD) in a glacially influenced shelf succession (Eyles et al., 1998). Vertical scale is in meters.

large-scale cross-stratified facies because of a lack of deep channels and an abundance of coarse debris (Miall, 1992). Glacial lake facies include distinctive rhythmically laminated silts and clays that record seasonal patterns of sedimentation (varves).

Varved facies dominate glacier-fed lakes (Figure 7). Varve thickness typically decreases upward in measured profiles recording ice retreat. So-called proximal varves may be many meters thick and composed of ripple cross-laminated sands.

Figure 6 Facies model for subglacial depositional system (Figure 2) involving deposition of successive sheet-like units of deformation till.

Till-like sediments may form in ice-contact glacial lakes where icebergs drop coarse sediment into bottom muds (rainout diamict). These are discriminated from tills proper by consideration of their geometry (typically blanket-like, resting conformably on underlying deposits) and the associated glaciolacustrine facies with which they are conformably interbedded. Local deformation and incision result from the scouring of the lake floor by drifting ice masses such as icebergs (Eyles et al., 2005).

Supraglacial Depositional System

The subglacial depositional system is often partially covered by sediments that were transported on the ice surface (Figure 8). These supraglacial sediments were lowered onto the underlying till plain as the underlying glacier melted. A distinctive hummocky topography marked by craters (kettle holes) forms when buried ice melts and overlying sediment collapses. This topography is common at the margins of valley glaciers that transport substantial quantities of rubble rock fall debris derived from adjacent rock walls. Boulderly supraglacial debris can blanket the immediate ice margin, insulating it from melt and thereby creating a belt of hummocky ice-cored sediments underlain by subglacial sediments and landforms. This is the hallmark of the glaciated valley depositional system. In addition, large volumes of sediment accumulate between the glacier and the valley sidewalls. With ice retreat, lateral moraine ridges left perched on the valley sides are quickly destroyed by mass wasting. Mass flow and meltwater processes rapidly convert the glacial fill of a confined valley into thick accumulations of outwash gravel and sand. The term proglacial has been used in reference to a

short-lived phase of intense reworking and sediment transport by rivers immediately after deglaciation.

There is still much uncertainty regarding the origin of the hummocky terrain left behind in flat mid-continent regions by Pleistocene ice sheets. This distinctive topography extends across huge tracts of the glaciated portion of the mid-continent North American plains underlain by soft Mesozoic rocks. This terrain was initially regarded as a supraglacial deposit akin to that left by valley glaciers, but the process of how thick sediment could accumulate on top of the ice sheet was never clear. The composition of hummocky moraine offered clues; it is composed of the same clay-rich till found in nearby drumlins into which it passes. Indeed, transitional landforms can be recognized where the formerly flat till plain was pressed into hummocky streamlined shapes (humdrums). It is now recognized as the product of the pressing of a soft till substrate, under portions of the ice margin that stagnated (Boone and Eyles, 2001). Here, the extensive development of a soft bed in mid-continent reflects the presence of weak, fine-grained rock. Such topography may identify relatively faster flowing ice streams within the ice sheet (Hart, 1999) moving across a soft bed of overpressured shales. Large rafts of glaciotectionized soft rock were moved below the ice.

Marine Glacial Depositional Systems

The term glaciomarine identifies processes or deposits that occur within a narrow zone in direct contact with the margin of a glacier (or ice sheet) that reaches sea level. The term

Figure 7 Facies models for glaciolacustrine depositional system (Figure 2) with (a) ice-contact and (b) non-ice-contact types. Typically, the deposits of non-ice-contact lakes are strongly influenced by seasonal variations in the volume of meltwater entering the basin, reflected in varved sedimentation. (c) Slumping on oversteepened delta fronts (I–V) in winter may complicate this.

ice-contact marine or proglacial marine are synonyms for marine settings where glacial influences predominate. Outside this zone and away from direct contact with the ice margin is the glacially influenced marine environment where marine

processes, not glacial, dominate. In areas affected by Quaternary glaciations, glacioisostatic depression and subsequent postglacial uplift of coastal margins have left widespread marine glacial deposits exposed above sea level. Knowledge of

Figure 8 (a) Facies model for supraglacial deposition where ice surface is covered by debris. Melt of buried ice results in widespread slumping and flow of sediment as it is lowered onto subglacial sediments below. Final ice melt produces a resulting in a chaotic hummocky terrain. (b and c) Typical hummock stratigraphy showing: (1) debris flow diamict with rafts of other sediments, (2) diamict melted out from dead ice (meltout till), (3) outwash gravels that accumulated in troughs, (4) glaciotectionically deformed subglacial sediment or rock. Faults and slump structures are common throughout.

marine glacial depositional systems is also key to interpreting the pre-Pleistocene record of glaciation given selective preservation of offshore basinal facies (see below).

Glaciomarine Depositional System

The glaciomarine depositional system occurs where an ice margin terminates in water (Figure 9). When advancing, ice will commonly bulldoze an underwater ridge (morainal bank) in front. This deposit is subsequently overridden to produce thrust sediment and deformation tills (Boulton et al., 1996). A retreating glacier will leave morainal banks on basement highs where ice could ground and stabilize temporarily (e.g., Powell and Domack, 1995). This setting is highly dynamic because the ice margin is partially floating and thus unstable, losing mass by calving icebergs. This environment is dominated by strong jets of meltwaters issuing below water at the ice front, delivering coarse gravel and sand facies deposited on subaqueous meltwater fans (e.g., Hunter et al., 1996). Deposition by turbidity currents results in a wide variety of massive and graded gravel and sand facies found in multistorey cross-cutting channels. Plumes of suspended sediment are also released. These produce blankets of massive mud where mud rains out in quiet water areas; pebbly muds form where

ice-rafted debris is dropped to the seafloor. Tides interact with plumes to produce rhythmically laminated mud facies; seasonal varved deposits may also occur. Ice proximal submarine outwash facies rest unconformably on lowermost subglacially deposited and glaciotectionically deformed facies such as till.

In general, glaciomarine deposits deposited along ice margins in water have a low preservation potential. These accumulations are usually destroyed by shallow marine erosion as a result of glacioisostatic uplift, by iceberg scour, and by downslope mass wasting. Typically, shallow water facies (beach gravels) truncate underlying glaciomarine facies.

Glacially Influenced Marine Depositional System

'Glacially influenced' is an umbrella term for deposits accumulating in the more remote parts of a glaciated basin beyond the direct reach of glaciers (i.e., distal to the glaciomarine realm; Figure 2). The depositional system is fed by glacial sediment that has been extensively reworked by currents or gravity. Areas affected by glacioisostatic movements of the crust created by the weight of the ice sheet, or glacioeustatic sea-level changes (or floating icebergs), are also said to be glacially influenced. The setting necessarily encompasses a much

Figure 9 Facies model for glaciomarine depositional system near a tidewater glacier margin (see [Figure 1\(b\)](#)). (1) Glaciotectionized marine sediments or bedrock, (2) till, (3) stratified accumulation of diamict deposited by slumping of till and other debris, (4) mud with ice-rafted debris, (5) channelled gravel and sand of submarine fan, (6) slumps and sediment gravity flow facies ([Figure 3\(b\)](#)), (7) iceberg scour and plume of suspended sediment, (8) push ridge. The entire sediment package commonly takes the form of large ridges (morainal banks) reflecting short-lived pauses in the ice margin as it retreats.

broader range of environments across continental shelves and slopes (e.g., [Anderson, 2002](#); [Eyles et al., 1998](#)). Here, a glacial influence is expressed in the form of rapid changes in water depths brought about by glacioeustasy (the removal of water from the oceans to build ice sheets) and glacioisostasy (the unloading and loading of the lithosphere by removing and returning water from the oceans during glaciations, or direct loading by ice sheets). These two processes act together to create complex spatial and temporal variations in water depths and depositional conditions in different areas of the same sedimentary basin. Detailed examination of glacial facies and disconformities in vertical successions will provide data as to whether water depths were increasing or decreasing ([Miall, 1997](#)). It is dangerous however to interpret these as necessarily reflecting changes in sea level per se; sea level may have remained unchanged with the basin floor itself responding to different loads. For this reason, changes in water depths evident from the study of stratigraphic successions are best described as relative sea-level changes, not in absolute (eustatic) sea level.

Floating ice masses and the introduction of coarse ice-rafted debris, and 'rainout' of mud from plumes of suspended sediment are other significant distal glacial influences on otherwise normal marine sedimentation processes. Several times during the last 100 ka, huge armadas of icebergs were released from rapidly calving margins of Northern Hemisphere ice sheets and are recorded as distinct ice-rafted horizons in mud ([Andrews, 1998](#)); coarser layers of ice-rafted facies are known from the ancient record ([Eyles et al., 1998](#)). Blankets of stony mud

subject to repeated winnowing and scour by iceberg keels (ice keel turbation) cover the mid and outer parts of glacially influenced shelves below storm wave base ([Woodworth-Lynas and Dowdeswell, 1994](#)). These substrates host a wide range of infaunal and epifaunal organisms reflected in diverse ichnofacies types ([Eyles and Vossler, 1992](#)). Deep-water muds pass shoreward into inner shelf areas, and interfinger as fairweather deposits within thick storm-influenced and shore-face sands.

Most glacially influenced continental shelves are not major repositories of glacially influenced marine facies. Water depths are too shallow, so their floors are current-swept and most shelves are undergoing uplift or only slow subsidence. This results in the inability to create space for (accommodate) substantial thicknesses of sediment. Large areas were exposed at times of glacioeustatic sea-level lows and scoured by ice sheets or large melt rivers. Typically, shelves are characterized by condensed successions where deposits of only the last glaciation are found resting on major erosion surfaces. Some glacially influenced continental margins (e.g., Antarctica) are slowly subsiding. These show a well-defined subsurface structure (evident on seismic records) of horizontal 'topsets' composed of relict shelf sediments that have aggraded vertically through time and which may include subglacial sediments ([Anderson, 2002](#); [Dowdeswell and O'Cofaigh, 2002](#)).

Along glaciated continental margins, the bulk of glacial sediment accumulates in deep-water basins on the continental slope or at its base. These experience enhanced sediment

supply at times of lowered sea level when rivers or glaciers discharge sediment directly to the shelf edge (e.g., Hooke and Elverhoi, 1996). Sediments pushed across the shelf under glaciers are transported downslope at the shelf edge by slumping and sediment gravity flows and promote progradation of the slope (Anderson, 1999). The outward growth of the slope during successive glaciations produces large foresets of downslope-thickening wedges of sediment clearly evident on deep seismic records.

Using Glacial Lithofacies to Unravel Pre-Quaternary Glacial Climates

Study of modern Quaternary glacial facies has been instrumental in understanding ancient cold climates in Earth history. The oldest sedimentary rock so far known is of 3.8 Ga and provides the first record of running water. In the sedimentary record of ancient cold climates, there are seven episodes of extended glaciation (glacioeras). There are two Precambrian glacioeras (the late Archean–early Proterozoic ca. 2.8–2.3 Ga and the Neoproterozoic ca. 750–600 Ma). These are followed by the three Phanerozoic glacioeras of the end Ordovician (ca. 440 Ma), the late Paleozoic (the longest: ca. 350–250 Ma), and the late Cenozoic glacioera, which is the best documented (but where major uncertainties still remain as to causal mechanisms). This last glacioera was the culmination of global cooling after 55 Ma and commences with the growth of the Antarctic Ice Sheet at about 40 Ma. Large continental ice sheets only appear much later in the Northern Hemisphere (mostly after 3 Ma). Their extent was controlled by Milankovitch astronomical variables creating Pleistocene glaciations and interglacials. Mountain glaciers probably existed for much of Earth's history but left no record, and the length of apparent nonglacial intervals without significant ice covers (such as the mid-Proterozoic) awaits explanation. The removal of water from the oceans during Ordovician glaciations is considered by some to be the main driver behind extinction events in marine biota (e.g., Brenchley et al., 2003).

The pre-Pleistocene glacial record is fertile ground for research because much of it remains to be investigated using detailed facies analysis. In general, glacial terrestrial depositional models are of limited use in examining this record because glacially influenced marine facies dominate Earth's ancient (pre-Pleistocene) glacial record (e.g., Allen et al., 2004; Eyles, 1993). This simply reflects the selective preservation of offshore basinal facies. The origins of ancient glaciations result from the interplay of tectonics creating high ground (tectonotopography), principally by rifting of large plates, the changing paleogeography and oceanography of the planet arising from rifting and plate migrations, variations in the solar flux, astronomical Milankovitch variables, and reductions in atmospheric CO₂ created by weathering of sediment. One school of thought argues that Precambrian and Phanerozoic glacioeras were radically different, with older glaciations being of global extent (e.g., Hoffman and Schrag, 2002). This model is the subject of much debate and opposition from those in favor of a uniformitarian approach applying knowledge of modern glacial depositional systems and facies to the reconstruction of ancient conditions (Eyles and Januszczak, 2004).

Introduction

The glaciomarine environment refers to that part of the world's seas affected by glaciers and ice sheets, which influence the ocean through the delivery of meltwater, sediment, and icebergs (Figure 1). Today, such environments are only found in high-latitude regions such as Antarctica, Greenland, and Svalbard (Figure 2), but during Quaternary full-glacial periods they were more extensive and many midlatitude oceans were affected by glaciers (Dowdeswell and Scourse, 1990). In general, glaciomarine environments can be characterized by those affected by grounded tidewater glaciers (nonfloating) and those affected by ice shelves (floating) (Anderson and Ashley, 1991). Modern, large ice shelves are only found around Antarctica, and non-floating glacier margins are more common. This pattern appears to have been similar during the Quaternary.

Glaciomarine sediments comprise debris deposited in the marine environment by release from either grounded or floating ice. Such sediments have a greater preservation potential than terrestrial glacial sediments, as the depositional setting of deep-ocean basins situated beyond the ice-sheet margin means that they are less likely to be eroded and reworked during successive glacial advance–retreat cycles. They preserve a sedimentary archive of past environmental change in terms of the waxing and waning of continental ice sheets and associated changes in oceanography and climate. Glaciomarine sediments can be deposited by a variety of processes including the rain-out of ice-rafted debris (IRD), suspension settling of fine-grained sediment from plumes, and a variety of sediment gravity flow processes (Figures 1 and 2). In addition, the effects of postdepositional processes which act to rework glaciomarine sediments, such as ploughing by grounded icebergs (Figure 3) and bioturbation, can also play an important role. The resulting sediments therefore tend to be both texturally and sedimentologically complex.

Glaciomarine Sediments in the Quaternary Record

Depositional Architecture and Sedimentology of Ice-Proximal Settings

Quaternary glaciomarine sediments may be preserved on land above present sea level as a result of glacioisostatic rebound, and they may also be found below present sea level on continental margins where they were deposited during former ice-sheet advances. A variety of glaciomarine landform–sediment assemblages have now been identified in the Quaternary record using sedimentological, geomorphological, and marine geophysical techniques, coupled with reference to modern glaciomarine analogs.

Grounding-line fans

Grounding-line fans (also referred to as 'subaqueous outwash fans') are sediment accumulations deposited where

subglacial meltwater, debouching from an englacial and subglacial tunnel, enters the sea, discharge velocity is rapidly reduced, and sediment is deposited (Powell and Molnia, 1989). The ice-proximal location of grounding-line fans means that they are characterized by texturally and sedimentologically heterogeneous lithofacies. These fans typically have a complex geometry with fine-grained, laminated, and stratified sediments incised by a variety of coarser-grained channelized facies.

Cheel and Rust (1982) have developed a facies model for grounding-line fans based on investigations of late Quaternary glaciomarine sediments (Figure 4). At the fan apex close to the subglacial tunnel mouth, clast-supported, imbricate boulder gravels record deposition from a subaqueous jet emanating from the tunnel (Figure 5). These boulder gravels give way down fan to a series of steep-sided channels containing horizontally stratified sands with discontinuous beds of imbricate gravel, massive sands, and subhorizontally laminated sands. Facies between the channels comprise, proximally, cross-stratified and massive-to-normally graded sands and fine gravels, and, more distally, climbing ripples with occasional silt drapes.

Morainal banks

Morainal banks are subaqueous moraines deposited along grounding lines during intervals of glacier-terminus stability (Figure 6(a)). They are commonly composed of coalescent grounding-line fans (Powell and Molnia, 1989). The elongate morphology of morainal banks reflects their origin by deposition from a series of point sources along the ice-front, as well as by ice-marginal fluctuations that act to bulldoze and squeeze sediment along the grounding line. Like grounding-line fans, lithofacies within late Quaternary morainal banks tend to be sedimentologically and texturally variable, reflecting the dynamic nature of the depositional setting where high ice-proximal sedimentation rates combine with glacier-margin fluctuations to both deposit and rework sediment. This typically results in the formation of thick, stacked sequences of heterogeneous debris ranging from boulder gravels to mud (Figure 6(b)). Sediment gravity flow processes are particularly common within morainal banks. In a detailed sedimentological study of a late Quaternary glaciomarine morainal bank in northeast Ireland, McCabe et al. (1984) showed how the moraine-complex records fan sedimentation against a retreating tidewater glacier margin. Sediments within the morainal bank are dominated by sediment gravity flow facies including massive and variably stratified diamicts deposited as subaqueous debris flows, parallel laminated, and massive sands deposited from density underflows, as well as channelized normal- and inversely graded gravels which record deposition from high-density sediment gravity flows.

Morainal bank size is controlled by the duration of grounding-line stability, debris supply, and ice-proximal

Figure 1 Schematic representation of sedimentation in an ice-contact glaciomarine environment fed by a tidewater glacier (not to scale).

Figure 2 Photograph of suspended sediment plumes emanating from tidewater glacier front, Spitsbergen. Photograph by J.L. Wadham.

sedimentation rates. In the Canadian Arctic, emergent morainal banks from the last glaciation range from diamict veneers that are less than 1 m thick, to over 10 m thick accumulations of mud, sand, and diamict that are the result of the coalescence of grounding-line fans. Sediments include

rhythmically laminated muds deposited by suspension settling from turbid plumes (Figures 1 and 2; Ó Cofaigh and Dowdeswell, 2001), diamict facies ranging from massive tills to weakly graded subaqueous debris-flow deposits, and iceberg-rafted deposits (Figure 6(c) and 6(d)).

Figure 5 Late Quaternary grounding-line fan sediments, Eastern Ireland. Massive, *a*-axis imbricate, boulder gravels deposited from subaqueous jet, in a proximal grounding-line fan depositional setting.

Deltas

Where sedimentation rates are high, grounding-line fans and morainal banks can aggrade to sea level and form ice-contact deltas (Figure 7(a); Powell, 1990). Such deltas often form isolated flat-topped mounds, located on topographic highs that acted as pinning points during glacier retreat (Figure 7(b)). They are characterized by steep ice-contact slopes and pitted surfaces due to the melt-out of buried ice. Such deltas commonly are Gilbert type with a tripartite internal structure of topsets, foresets, and bottomsets (Figure 7(c)). Topsets are essentially braided river deposits, and consist of subhorizontally bedded, massive gravel. Foreset beds are typically dominated by gravelly and sandy sediment gravity flow facies (Figure 7(d)), with occasional diamict beds deposited by debris flows. They grade downslope into bottomset beds of massive and graded sand and silt (Figure 7(e)). Prodelta distal bottomset beds are composed of more massive finer-grained silts and clays that often contain marine macrofauna (Figure 7(f)). Sediments on ice-proximal slopes typically contain a range of deformation structures related to glaciotectonic disturbance, and the melt-out of buried ice and/or slope collapse associated with glacier retreat.

Grounding-zone wedges

The term grounding-zone wedge (also termed 'till delta' and 'grounding-line wedge') refers to sediment depocenters comprising low-gradient, dipping beds of diamict that are unconformably overlain by horizontal beds of deformation till. Such features are believed to be associated with glaciers that are underlain by a deforming till layer. In the Quaternary record they are being increasingly described in marine geophysical

investigations of high-latitude continental shelves (e.g., Davies et al., 1997). In plan view they appear on geophysical records as sedimentary ridges, orientated transverse to former ice flow. They mark stillstands of the ice-sheet margin during deglaciation and their formation requires that the ice margin was stable for some period of time. Although they are not necessarily associated with floating ice, they are generally believed to mark the location of the transition from grounded to floating ice. Excellent examples of grounding-zone wedges have been imaged on marine geophysical records from Antarctica (e.g., Anderson, 1999; Shipp et al., 2002). There, geophysical profiles show that they are characterized by a back-stepping pattern reflecting progressive ice-sheet retreat (Figure 8). Sediment cores and seismic records suggest that they are composed of poorly sorted diamictic sediment.

Glaciomarine Sedimentation on High-Latitude Continental Margins

High-latitude continental shelves are typically characterized by deep cross-shelf bathymetric troughs separated by intervening shallow banks (Figure 9). These troughs extend across the shelf from fjords, which dissect the mountainous hinterland of adjacent landmasses. Examples of this pattern have been well documented from the Norwegian–Greenland Sea and Antarctica (e.g., Anderson, 1999; Dowdeswell and Ó Cofaigh, 2002; Elverhøi et al., 1998). During the Quaternary, ice sheets expanded across continental shelves through these troughs, in many cases reaching the edge of the continental shelf, and depositing a characteristic suite of sediments and landforms.

Within the troughs, streamlined subglacial bedforms in the form of drumlins, mega-scale glacial lineations and flutings (Figure 10) record the former presence of fast-flowing, ice-sheet outlets (paleo-ice streams) and can be used to infer both the former flow direction and style (streaming in the troughs vs. nonstreaming on adjacent banks; e.g., Canals et al., 2000; Ó Cofaigh et al., 2005). Sediments recording ice-sheet advance on the shelf normally comprise massive overconsolidated till. In the bathymetric troughs, however, these high shear strength tills are characteristically overlain by highly porous, massive tills characterized by low shear strengths, which are the product of subglacial sediment deformation during streaming flow (Dowdeswell et al., 2004). The streamlined subglacial bedforms that record the presence of paleo-ice streams within the troughs are typically composed of these weak tills. These subglacial sediments are overlain by a variety of glaciomarine facies deposited during ice-sheet retreat including grounding-zone deposits in the form of massive diamict and poorly sorted gravel, as well as massive and laminated mud. The precise nature of such sediments will depend on a variety of factors including the rate of retreat and availability of meltwater. Sequences may be capped by organic-rich, open-marine sediments.

Where these ice streams reach the continental shelf edge during successive glacial maxima, large volumes of subglacial sediment are released at the grounding line and delivered to the upper continental slope. This sediment is remobilized downslope under the influence of gravity by debris-flow processes resulting in the formation of low-gradient (in some cases $<1^\circ$) fan-shaped sediment accumulations in front of the trough mouths (Figures 9(b) and 11). These trough-mouth fans are

Figure 6 Late Quaternary morainal banks. (a) Arcuate morainal bank inset between fjord side and ice-molded bedrock highs, Ellesmere Island. The morainal bank was deposited by a fjord glacier during retreat from the Last Glacial Maximum. (b) Section in morainal bank, Dundalk Bay, Eastern Ireland. Note the thick sequence of stacked, texturally heterogeneous sediments including diamict, gravel, sand, and silt that is characteristic of the ice proximal, subaqueous depositional setting of morainal banks. (c) Horizontally laminated sand-silt couplets with occasional small dropstones, interpreted as suspension deposits from turbid overflow plumes with background iceberg-rafted debris, Ellesmere Island, Canadian Arctic. (d) Stacked beds of massive, matrix-supported diamict with outsized clasts, deposited by subaqueous cohesive debris flows, Ellesmere Island, Canadian Arctic.

Figure 7 Late Quaternary raised marine, ice-contact deltas and sediments, Canadian Arctic. (a) Terraced, ice-contact fjord delta. (b) Marine limit ice-contact deltas at fjord head, with distal accumulations of pro-delta silty muds. The deltas are banked against ice-molded bedrock highs which acted as pinning points during deglaciation facilitating a stillstand of the retreating glacier margins and delta formation. (c) Internal stratigraphy of ice-contact Gilbert-type raised marine gravel delta. Note the horizontally bedded topset gravels which unconformably overlie foreset beds comprising planar crossbedded gravel. (d) Delta foreset bed composed of normally graded open-work gravels deposited by high-concentration turbidity current. (e) Delta bottomset beds consisting of normally graded sands with silty mud cap. Figure 7 (Continued)

major sedimentary depocenters and are a prominent feature of the Quaternary record of high-latitude continental margins (Dowdeswell et al., 1998; Vorren et al., 1998). Major periods of fan progradation are associated with relatively short intervals when ice streams terminated at the shelf edge during glacial maxima, and their sedimentary record is dominated by stacked debris flows (Figure 11). The debris flows form packages which may be separated by thinner layers of hemipelagic sediments deposited during interglacials or interstadials. Trough-mouth fans therefore contain an archive of past ice-sheet expansion and recession. Adjacent areas of the continental slope can be characterized by sediment slides, although such sediment failures have also been documented on the fans themselves. Slide deposits are often characterized by a blocky chaotic appearance on acoustic records, and associated sediments include turbidites related to emplacement of the slide.

Ice-Rafted Debris

Grain Size of IRD: Definitions and Problems

Transport by floating ice, whether it be icebergs or sea ice, is the dominant mechanism by which glacial sediment is delivered

to ice-distal glaciomarine environments and the deep-ocean basins. The term IRD refers to the material carried on, and within, this floating ice (Figure 12). The more specific terms 'iceberg-rafted debris' and 'sea-ice-rafted debris' differentiate between sediment transported by icebergs and sea ice, respectively. The emphasis here is on debris transported and deposited by icebergs. Initial research using IRD in Quaternary paleoceanographic investigations was mainly focused at Milankovitch timescales. It was not until the identification of the 'Heinrich layers' and recognition that these sediments related to enormous, millennial-scale discharges of icebergs ('Heinrich events') from the last North American ice sheet, that the use of IRD as a proxy by the paleoceanographic community became widespread.

Paleoceanographic studies use one of several grain size envelopes to define IRD. Most investigators use counts of the $>150\ \mu\text{m}$ fraction. Others have focused on the number of visible particles greater than 2 mm in diameter on core X-rays for a specified depth interval (usually 1 or 2 cm). This avoids the potential problem with fine grain sizes, whereby, close to a continental source, delivery of particles $<0.2\ \text{cm}$ in diameter may be by processes other than iceberg rafting. A problem with this, however, is that such coarse-grained material may be rare in

Figure 8 Marine geophysical records of grounding-zone wedges on the continental shelf around Antarctica. (a) TOPAS record of back-stepping grounding-zone wedges deposited during ice-sheet retreat from the Last Glacial Maximum, Marguerite Bay, Antarctic Peninsula. The bedforms record the former flow of a grounded paleo-ice stream at, or immediately following the Last Glacial Maximum. (a) Drumlins and lineations formed in sediment and bedrock. (b) Mega-scale glacial lineations. The lineations have elongation ratios of up to 90:1, a maximum height of 15 m, and widths range from 130 to 300 m. Modified from Ó Cofaigh C, Dowdeswell JA, Allen CSA, et al. (2005) Flow dynamics and till genesis associated with a marine-based Antarctic paleo-ice stream. *Quaternary Science Reviews* 24: 709–740.

the deep sea. Andrews (2000) points out that it is often implicitly assumed in paleoceanographic studies that the relative abundance of IRD is similar for all size fractions from fine-sand through to grains >2 mm across (i.e., a peak in the >2 mm fraction will be matched by a peak in the >250 μm fraction which will be matched by a peak in the >125 μm fraction, and so on). However, as he notes, in reality, this is unlikely, since the 63–2000 μm fraction is least well represented in glacial sediments, whereas the <63 μm fraction is far more abundant.

A further problem is that of distinguishing between sea-ice-rafted debris and iceberg-rafted debris. Limited data suggest that sea-ice-rafted sediment is fine-grained (silt and clay), whereas icebergs are more likely to contain debris of heterogeneous grain size. This reflects the processes of debris entrainment where sea ice predominantly incorporates sediment by eolian processes and freeze-on of turbid seawater. It should be noted however, that anchor ice can incorporate coarse, glacier derived, material in coastal and shallow-marine settings.

Case Study of IRD in the Deep Sea: The Heinrich Layers

Heinrich (1988) first documented the occurrence of six sand-rich IRD layers in deep-sea cores from west of Spain and Portugal. Subsequent studies found similar correlative layers with high carbonate contents in a band approximately coinciding with the IRD belt in the North Atlantic (Andrews and Tedesco, 1992; Bond et al., 1992; Figures 13 and 14). These 'Heinrich layers' record the episodic collapse of the Laurentide Ice Sheet in the Hudson Strait region of eastern Canada on at

least six separate occasions in the last 69000 years, during which enormous numbers of icebergs were delivered into the North Atlantic ('Heinrich events'). The most recent estimate for the duration of Heinrich layer formation is 500 ± 250 years (Hemming, 2004). A Hudson Strait source for the icebergs is supported by the large fraction of detrital carbonate contained within the layers (see Internal characteristics), and the strong distance decay eastward in Heinrich layer thickness from the mouth of Hudson Strait, which is floored by Paleozoic limestone, into the North Atlantic (Dowdeswell et al., 1995; Figures 14 and 15).

Internal characteristics

In the North Atlantic, Heinrich layers are characterized by unusually high concentrations of IRD, low Foraminifera abundance but with the planktonic species *Neogloboquadrina pachyderma* (left-coiling) dominating, sharp lower contacts demonstrating rapid onset of IRD deposition, and detrital carbonate contents of 20–25% (although H6 does not appear to be as carbonate-rich as the other five; Bond et al., 1992; Hemming, 2004; Figure 14). Decreases in planktonic $\delta^{18}\text{O}$ also occur in the layers implying marked reductions in sea surface salinities during their deposition. These characteristics apply to ice-distal Heinrich layers, that is, those deposited in the North Atlantic where the Heinrich layer thickness can be <5 cm. This contrasts with the more ice-proximal regions of the Labrador Sea, close to Hudson Strait. Here, Heinrich layer thickness can be more than 3 m, and detrital carbonate contents are 40–50%. Furthermore, ice-proximal Heinrich layers exhibit considerable sedimentological variability and record a

Figure 11 Trough-mouth fan sedimentation on high-latitude continental margins. (a) GLORIA 6.5 kHz side-scan sonar image of debris-flow lobes on the Bear Island Fan. The dark lines running approximately north–south across the image are ship tracks; (b) 3.5 kHz sub-bottom profile through debris flows on the Bear Island Fan, showing the stacked nature of the flows and their convex upper surface. Both (a) and (b) are modified from Dowdeswell JA, Elverhøi A, and Spielhagen R (1998) Glaciomarine sedimentary processes and facies on the Polar North Atlantic margins. *Quaternary Science Reviews* 17: 243–272. (c) Conceptual model for trough-mouth fan deposition in front of an ice stream reaching the continental shelf edge. Debris-flow activity and suspension settling from turbid meltwater plumes dominate sedimentation. (1) Debris flows sourced from glaciogenic sediment at the shelf edge; (2) buoyant turbid meltwater plume; (3) turbidity current formed by downslope evolution from a debris flow; (4) subglacial till extruded along the ice-stream front/grounding line; (5) subglacial (deformation) till; (6) slump generated debris flow; (7) stratified sediments deposited by suspension settling from meltwater plumes, contour-current and minor turbidity-current activity; (8) iceberg rafting.

Figure 12 (a) Debris of heterogeneous grain size on the surface of an iceberg offshore of the Antarctic Peninsula. The largest clasts are about 0.5 m in diameter. Note the subangular to subrounded shape of the clasts which indicates subglacial transport. (b) Core X-radiograph of an IRD layer of gravelly sand contained within weakly laminated, clast-poor mud. Note the sharp upper and lower contacts of the layer.

Figure 13 Locations of cores that contain Heinrich layers. Fully black filled circles indicate that carbonate-rich IRD is present in all Heinrich layers identified; half-filled circles indicate that carbonate-rich IRD is absent in some of the Heinrich layers identified; open squares show no carbonate-rich IRD in Heinrich layers. The solid black pattern is the distribution of limestone and dolomite bedrock and the thick solid line is approximate maximum limit of ice sheets during the last glaciation. The westward increase in thicknesses of the Heinrich layers is indicated by the increase in the size of the circles. Modified from Bond G, Heinrich H, Broecker W, et al. (1992) Evidence for massive discharges of icebergs into the North Atlantic during the last glacial period. *Nature* 360: 245–249.

Figure 14 Correlation between cores containing Heinrich layers from the Dreizack Seamount area with DSDP site 609 from the North Atlantic, including summary of radiometric, planktonic, $\delta^{18}\text{O}$, foraminiferal, and lithic measurements. Heinrich layers H1–H6 are marked. Modified from Bond G, Heinrich H, Broecker W, et al. (1992) Evidence for massive discharges of icebergs into the North Atlantic during the last glacial period. *Nature* 360: 245–249.

variety of processes other than iceberg rafting, including turbidity current sedimentation and deposition from the nepheloid layer (Hesse and Khodabakhsh, 1998).

Mechanisms and controls

Three main explanations have been proposed to explain the Heinrich layers:

1. The binge–purge model (MacAyeal, 1993) is a glaciological explanation. A large ice sheet will build up gradually through time (the ‘binge’ stage) until a critical threshold (determined by geothermal heat flux, advection of heat from the ice-sheet surface and strain generated heat) is exceeded and the ice-sheet bed changes from a frozen to a thawed state. This results in rapid ice flow and a major pulse of icebergs – the ‘purge stage’ – giving a Heinrich event. Successive surges of the Laurentide Ice Sheet through Hudson Strait were believed to have been facilitated by soft unconsolidated sediment on the floor of the strait. MacAyeal (1993) calculated a periodicity of about 7000 years for the cycle which agrees with the observed periodicity of the Heinrich events.
2. Johnson and Lauritzen (1995) proposed that repeated outburst floods from a subglacial lake in Hudson Bay produced major pulses of freshwater into the North Atlantic when the ice dam at the mouth of Hudson Strait failed. Such large meltwater discharges would help to explain the abundance of meltwater sediments in ice-proximal Heinrich layers. However, although such a lake could have formed during the early phases of ice-sheet build-up, its presence during the Last Glacial Maximum (LGM) appears to have been unlikely (Andrews, 1998).
3. Hulbe et al. (2004) explain the Heinrich events through the catastrophic collapse of ice shelves fringing the Laurentide Ice Sheet. They argue that ice shelves formed around the ice-sheet margin during extreme cold periods. Subsequent climate warming resulted in their catastrophic collapse and the production of major pulses of icebergs (cf. collapse of the modern Larsen B Ice Shelf in Antarctica). A problem with this model is that available paleoclimatic records show that the Heinrich events began during cold intervals and thus preceded climate warming. Indeed, correlation of the North Atlantic IRD record with the Greenland ice cores shows that each Heinrich event was actually the culmination of a long period of climate cooling and was then followed by an abrupt shift to a warmer climate (Bond et al., 1999).

Figure 15 Map showing thickness in centimeters of Heinrich layers H1 (a) and H2 (b) in the North Atlantic based on whole core magnetic susceptibility data. Stipple indicates adjacent landmasses and cross-hatching refers to the generalized locations of ice sheets at the time of Heinrich layer deposition. Modified from Dowdeswell JA, Maslin MA, Andrews JT, and McCave IN (1995) Iceberg production, debris rafting, and the extent and thickness of Heinrich layers (H-1, H-2) in North Atlantic sediments. *Geology* 23: 301–304.

Resolving the question of whether the Heinrich events were triggered by an internal instability within the Laurentide Ice Sheet or alternatively are an ice-sheet response to climate forcing, is critical to determining their underlying cause. Fundamental to this is the timing of the Heinrich events and how they correlate with climate records from the North Atlantic region. A near synchronous response of several ice masses around the North Atlantic might imply an external driver such as climate but this relies upon accurate fingerprinting of IRD to different ice-sheet sources, as well as robust chronological control (cf. the debate over

the ‘precursors’ to Heinrich events from European sources; Hemming, 2004). This topic is likely to remain central to research on IRD and Heinrich layers for some time to come.

Glaciolacustrine

D J A Evans, Durham University, Durham, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

The glaciolacustrine environment includes all ice-contact deep water bodies created by the damming of terrestrial drainage basins by glacier ice. Many small ice-dammed lakes exist in contemporary glacierized landscapes, especially in upland settings where the damming is often related to the abandonment of large moraine loops by receding glacier snouts. Such moraine-dammed lakes are unstable and have a tendency to become potentially hazardous, often creating highly damaging glacial lake outburst floods (GLOFs). Many of the sedimentation processes that operate in the glaciolacustrine environment are similar to those of glaciomarine settings, and so lake processes and forms are emphasized here. Very large, continental scale proglacial lakes existed around the margins of the receding Late Quaternary ice sheets, for example, the Lake Agassiz/McConnell system at the south and west margins of the Laurentide Ice Sheet (Teller, 1995, 2003) and the Baltic Ice Lake and western Russian drainage basins at the southern edge of the Eurasian/Fennoscandinavian ice sheet (Mangerud et al., 2004; Jakobsson et al., 2007). This has given rise to extensive and often thick blankets of glaciolacustrine deposits over formerly glaciated terrains.

Glaciolacustrine Processes

Significant in glaciolacustrine systems is the temperature stratification or thermal structure of lake water and its influence on the patterns of sediment transport and water flow (see Gustavson, 1975; Gilbert and Shaw, 1981; Smith et al., 1982; Smith and Ashley, 1985). The combination of surface heating and vertical mixing in a lake produces a three-layer water column comprising: (a) the epilimnion or upper layer of warm, low-density water; (b) the hypolimnion or lower layer of cold, dense water; and (c) the metalimnion or thermocline, which is a zone of rapid temperature change that separates the epilimnion and hypolimnion. Water inflow into glacier-fed lakes comes from a variety of sources, including direct input from glacier ice via englacial and subglacial portals, glacially fed rivers, and nonglacial rivers. Regions with marked seasonal temperature variations are characterized by maximum discharges of both water and sediment during the summer melt season. Upon entering a lake, the sediment-laden meltwater inflow undergoes an exponential decrease in velocity and thereby produces an expanding and decelerating plume. When viewed from the air, the outer edge of a turbid plume has a very sharp contact with the lake water into which it is discharging, and this marks the position of the 'plunge line' or the point where the plume sinks to reach lake water of similar density. If the density of the diluted inflowing water is less than the density of the epilimnion, it will rise to the surface as an

overflow, but if it is denser than the hypolimnion, it will flow along the bottom of the lake as an underflow. Interflows occur where the density of the inflowing water is intermediate between the dense, cold lake bottom water and the low-density, warm lake surface water, and will move along the thermocline (Figure 1). Other factors that govern the pattern of glacial lake sedimentation include the Coriolis effect, which causes plumes to be deflected to the right in the northern hemisphere and to the left in the southern hemisphere, and bathymetry, which can have a considerable impact on water circulation and associated sedimentation patterns.

Depositional processes operating in glaciolacustrine environments (Figure 2) include deposition from jets emerging from efflux points or subglacial/englacial tunnels (Powell and Domack, 1995), suspension settling, and melt-out/rafting from floating ice and icebergs (Thomas and Connell, 1985). In more proximal settings, the influx of sediment-laden water and the collapsing margins of depocenters give rise to subaqueous debris flows, which are either matrix-rich and cohesive or water-saturated and cohesionless (Lowe, 1976a,b; Nemec, 1990; Postma, 1986; Figure 3). Secondary or syndepositional disturbance and resedimentation can be affected by iceberg scouring (Woodworth-Lynas and Guigné, 1990; Teller, 2003) or the melt-out of buried glacier ice in supraglacial lake settings. The operation of these processes in space gives rise to a rapid proximal to distal fining of sediment assemblages, with the highest sediment concentrations being emplaced close to the efflux point in large depocenters called subaqueous fans, fed by hyperconcentrated flows or bedload traction carpets. Suspension sedimentation is the settling out of fine material from overflows, interflows, and underflows. Unlike marine environments where the salt content of the water aids the settling process, in lake water, suspended particles fall through the water column with a velocity that reflects the buoyant weight of the particle and the drag forces resisting motion, as explained by Stokes's Law.

Glaciolacustrine Sediments

The suspended sediment that gradually settles out from overflows and interflows forms blanket-like drapes, which typically display proximal to distal fining and thinning in lake basins (Smith et al., 1982) with additional patterns of thickening toward the right or left shore in the northern and southern hemispheres, respectively, due to Coriolis deflection (Smith and Ashley, 1985). Below shallow water, overflow and interflow deposits will tend to form massive muds and silts due to sediment mixing by bioturbation, wave disturbance, and wind-generated currents (Smith and Ashley, 1985), but below deeper water, the deposits are typically laminated, fining-up sequences of silt and clay rhythmities that record fluctuations in the

Figure 1 Simplified overview of the main glaciolacustrine processes, showing suspended sediment in light gray being delivered by interflow and underflow from the glacier margin and from a glacier-fed river by underflow, interflow, and overflow. Reproduced from [Teller JT \(1995\)](#) History and drainage of large ice-dammed lakes along the Laurentide Ice Sheet. *Quaternary International* 28: 83–92.

Figure 2 Diagrammatic representation of the range of depositional processes operating in a glaciolacustrine setting. An esker/subaqueous fan complex at 'A' feeds a prograding fan, which emerges from an englacial portal at 'B' and then grades distally into finer-grained rhythmites at 'C'. Iceberg dropstone, dump, and grounding structures are also depicted. Reproduced from [Thomas GSP \(1984\)](#) Sedimentation of a sub-aqueous esker-delta at Strathathie, Aberdeenshire Scottish. *Journal of Geology* 20: 9–20.

grain size and quantity of incoming sediment, due to daily, meteorological, or annual water and sediment discharge cycles ([Church and Gilbert, 1975](#); [Figure 4](#)). Short-term surge currents produce thin, normally graded laminae with sharp basal contacts, whereas annual rhythmic cycles produce distinct silt-clay couplets or varves, which reflect coarse sediment input from overflow and interflow plumes during the ablation season and fine-grained sediment input due to gradual suspension settling during winter, respectively ([Andren et al., 1999](#); [Ashley, 1975](#); [Eyles and Eyles, 1992](#); [Ohlendorf et al., 1997](#); [Palmer et al., 2008](#); [Figure 5](#)). In addition to providing chronological control for deglacial events in some regions, varve sequences have been linked to climatic and meteorological events in Late Quaternary sediment records (e.g., [Hambley and Lamoureux, 2006](#)).

In more proximal locations, the predominance of underflows tends to produce turbidites ([Mulder and Alexander, 2001](#)), which can be interbedded with rhythmites derived from interflows and overflows. Additionally, the operation of subaqueous debris flows gives rise to the accumulation of sequences of interdigitated, discontinuous beds of stratified diamictos. Turbidity currents produce a characteristic graded vertical sequence, known as the Bouma sequence ([Shanmugam, 1997](#); [Kneller and Buckee, 2000](#)), which from the bottom-up includes: (a) massive or normally graded sand or gravel, (b) planar-laminated sand, (c) ripple cross-laminated sand and silt, (d) interlaminated silt and/or clay, and (e) massive clay or silt ([Figure 6](#)). This reflects the gradual decrease in energy of a turbidity current on a lake bottom. Deposits indicative of cohesive debris flows tend to be sheet-like or lobate beds of massive,

Figure 3 Diagrammatic sketch of the range of gravity-driven sediment transport processes on subaqueous slopes with associated, schematic velocity profiles. Reproduced from Nemec W (1990) Aspects of sediment movement on steep delta slopes. In: Colella A and Prior DB (eds.) *Coarse-Grained Deltas*, pp. 29–73. International Association of Sedimentologists, Special Publication 10.

matrix-supported diamicton or muddy sands and gravels, often containing soft-sediment rafts ripped up from the substrate, and display planar or slightly scoured bases and basal shear zones (Ghibaudo, 1992). Cohesionless debris flow deposits are also typically dipping sheet-like or lobate masses whose bases are commonly erosive and form deep, channelized scours or chutes aligned downslope (Prior and Bornhold, 1990; Figure 7). Internally, they comprise gravel, sand, or pebbly sand, and may be well or poorly sorted, and may have incorporated rafts of underlying material to produce gradational 'welded' basal contacts. Individual flows may appear internally massive or inversely graded and rarely normally graded. Inverse grading at flow bases results from either dispersive pressure generated by colliding grains or kinetic sieving (Legros, 2002; Le Roux, 2003).

Ice-rafted debris (IRD) in glaciolacustrine environments is similar in appearance to that produced in marine settings.

It ranges from isolated clasts or dropstones, dropped onto the lake bed from floating ice, to iceberg dump mounds greater than a meter in height (Figure 8). Smith (2000) reports dropstone A-axis fabrics with high dip angles due to the penetration of stiff bottom sediments by clasts that fall vertically through the water column and hit the bottom nose-first. Thomas and Connell (1985) describe iceberg dump mounds based on Quaternary glaciolacustrine examples as planar-based symmetrical cones of coarse materials, occurring either in isolation or overlapping each other, or even stacked vertically and interstratified with finer-grained sediments. Asymmetrical cones can be produced where multiple dumping events result from repeated overturning of, or basal melt-out from, the same iceberg. A variation on this style of deposition are lake ice conveyor deposits which are linear ridges that mark the former locations of moats in lake ice covers (Hall et al., 2006).

Iceberg or lake ice scouring can produce specific sediment types and structures. Woodworth-Lynas and Guigné (1990) describe massive diamictos or ice-keel turbate produced by ice keel scouring, which can be very difficult to differentiate from nonstratified dropstone diamictos and even some subglacial tills. Some distinctive fault structures can be created by single iceberg grounding or ploughing events (Woodworth-Lynas and Guigné, 1990; Winsemann et al., 2007). These include laterally displaced sediment slices lying on either side of an iceberg plough trace (Woodworth-Lynas and Guigné, 1990) and soft sediment striations or grooves produced by floating lake ice (Eyles et al., 2005). Extensive and often complex disturbance can be introduced to glaciolacustrine sediment sequences where they have been deposited in supraglacial lakes (e.g., Eyles et al., 1987; Mager and Fitzsimons, 2007).

Figure 4 Typical rhythmically bedded sand, silt, and clay laminae, climbing ripples, and draped lamination in a glaciolacustrine depositional sequence on the foreland of Heinabergsjökull, Iceland. Note also the intraformational soft sediment deformation structures.

This includes intraformational soft-sediment deformation, normal faulting, water escape structures, and fluidization tracks, in addition to widespread subaqueous debris flow sedimentation.

Glaciolacustrine Depocenters

In common with marine settings, the landform–sediment associations of the depocenters typically observed in glaciolacustrine depositional environments include grounding-line or subaqueous outwash fans, subaqueous (De Geer) moraines, and deltas. Because of their ice-contact nature, many of the sedimentary sequences of these depocenters may display significant glaciotectionic disturbance (e.g., Phillips et al., 2002; Benn et al., 2004).

Subaqueous outwash fans accumulate at subglacial meltwater efflux points at the glacier–lake interface due to the sudden drop in stream velocity and the progradation of predominantly coarse-grained sediments at the base of the water column (Rust and Romanelli, 1975; Cheel and Rust, 1982; Figure 2). If sedimentation rates are high enough and/or the glacier snout remains relatively stationary, a subaqueous fan can build up to the water surface to form delta (Fyfe, 1990; Figure 9). Their association with subglacial tunnels often results in a close association with eskers where they can demarcate former glacier margins as esker beads (Banerjee and McDonald, 1975; Thomas, 1984; Figure 2). Coarse bedload deposited at the tunnel mouth due to efflux jet deceleration builds up steep, unstable slopes at the glacier margin. Slope failures and renewed sediment discharge from the tunnel mouth then feed cohesionless mass flows that transport sediment radially away from the depocenter and often evolve into turbidity currents. Glaciolacustrine subaqueous fans differ from their glaciomarine counterparts in that they are often finer grained due to the buoyancy and greater transport distances of marine plumes, and tend to contain underflow

Figure 5 Schematic diagram to show the influence of changes in runoff, wind, or gravitational transfer on the grain size variations in a single varve. The typical yearly signal of overall upward-fining is still visible and records the summer–winter change in sedimentation pattern. Figure 9 Three styles of glaciolacustrine depocenters based on the Salpausselka moraine assemblage in Finland (from Fyfe, 1990): (a) Gilbert-type delta, (b) subaqueous fan in shallow water, which may aggrade to form a Gilbert delta, and (c) subaqueous fan in deep water.

deposits or turbidites because the sediment-laden meltwater is generally denser than the surrounding lake water. Subaqueous fan sedimentary sequences therefore tend to display cross-bedded clinoforms of interdigitated stratified mass flow diamictites and coarse-grained sands and gravels (Bennett et al., 2002; Cheel and Rust, 1982; Figure 10). The latter comprise crude to well-developed foreset bedding dipping down from the fan apex at angles of 10–30°. The coarser-grained, poorly sorted, massive to normally graded gravels at the fan apex, deposited from high-density, cohesionless debris flows and gravelly traction carpets, grade distally into better sorted, finer grained facies, which document episodic turbidity currents and cohesionless debris flows, triggered by influxes of sediment-laden meltwater or slope failures on the fan surface (Postma et al., 1983).

Subaqueous moraines are deposited at or close to the grounding lines of water-terminating glaciers, and in glaciolacustrine settings have been variably termed sublacustrine moraines, cross-valley moraines, and De Geer moraines. [Benn and Evans \(2010\)](#) classify such moraines as either 'coalescent subaqueous fans', where they comprise large subaqueous moraine ridges formed at glacier grounding lines, or 'De Geer moraines' where they constitute smaller, narrow, and sharp-crested sub-parallel ridges commonly occurring in closely spaced clusters. Spectacular examples of coalescent subaqueous fans are the Salpausselka Moraines of Finland ([Figure 9](#)), which were deposited during stillstands of the southern margins of the Scandinavian Ice Sheet ([Fyfe, 1990](#)). Sediment exposures through such landforms typically exhibit a range of deposits,

from ice-proximal subglacial tills and glacioteconites derived from preexisting glaciolacustrine deposits to ice-distal subaqueous outwash, interbedded with cohesive to cohesionless debris flows (e.g., [Benn, 1996](#)). De Geer moraines commonly occur in fields of closely spaced ridges in association with subaqueous sediments and mark the intermittent retreat of water-terminating glaciers (e.g., [Aartolahti et al., 1995](#); [Andrews and Smithson, 1966](#); [Holdsworth, 1973](#)). They possess many of the morphological characteristics of terrestrial push moraines, such as steeper distal than proximal slopes, lobate forms with acute interlobe angles pointing up glacier, and truncated sections due to partial overriding by later moraines. Like subaqueous fans, De Geer moraines display a wide range of sediment types, from tills to stratified sediments, related to subglacial and glaciotectonic

Figure 12 Conceptual model to convey the relationship between ice-contact delta development and glacier retreat rate based on alpine glacial lakes during (a) glacier occupancy and ice-contact delta production, and (b) glacier retreat and ice-contact/supraglacial deposition of deltaic and distal sediments. Note the occurrence of delta collapse and the qualitative ratio of ice retreat to sedimentation rate. processes on ice-proximal slopes and the interdigitation of sediment gravity flow deposits and glaciolacustrine sediments on ice-distal slopes (e.g., Blake, 2000; Lindén and Möller, 2005).

Deltas form by a combination of fluvial aggradation above water level and progradation of bedload on the delta front due to deceleration of incoming streamflow. Fine-grained suspended sediment is carried beyond the delta by underflows, interflows, and overflows to be deposited in the deeper parts of the lake basin. Delta-front profiles usually display steep upper slopes, giving way to easier angled slopes toward the base of the delta, reflecting proximal-to-distal decreases in sedimentation rates and grain size. In a glacial context, deltas may form either as glacier-fed deltas, which receive sediment from proglacial meltwater streams following transport across an intervening land surface, or as ice-contact deltas, which are built out directly from glacier margins after evolving from subaqueous fans or moraines. Glacier-fed deltas are commonly the shallow-water Hjulström-type with gently sloping fronts or the deeper water Gilbert-type with steep fronts, in addition to the intermediate Salisbury-type (Church and Gilbert, 1975; Figure 11). The most common Gilbert-type deltas are recognizable from their characteristic tripartite sedimentary sequences of fluvial topsets, gravitational foresets, and underflow-fed bottomsets (Gustavson et al., 1975; Martini, 1990; Mastalerz, 1990; Postma, 1995). Ice-contact deltas commonly display similar sedimentary characteristics to those of glacier-fed deltas but, because they are deposited in ice-marginal or supraglacial settings, some important differences are readily apparent. Following glacier recession, an ice-contact delta will form an isolated plateau with a prominent, steep ice-contact slope at its ice-proximal end. They often also lie perched on topographic highs, where the only plausible source of sediment and water is a former glacier margin (Clayton et al., 2008), and will contain extensive surface pitting or kettle holes created by the melt-out of buried glacier ice. Ice-proximal facies will also often display evidence of subglacial deformation (Phillips et al., 2002; Benn et al., 2004) and/or slumping due to the melt-out of buried glacier ice or the removal of support from the ice-contact face. The relationship between ice-contact delta development and glacier retreat rate is depicted by the conceptual model of Shaw (1977) (Figure 12). At relatively stable glacier termini, a normal Gilbert-type delta will develop because of the low ice retreat to sedimentation ratio. If the terminus then retreats a short distance to another stable position, the ice-contact face of the delta will subside and be buried by a subsequent deltaic sequence. In contrast, if the glacier margin retreats rapidly, the increased ice retreat to sedimentation ratio will result in the replacement of delta formation with subaqueous fans and distal rhythmites.

Conclusion

Extensive and often thick blankets of glaciolacustrine deposits characterize the Quaternary sediment-landform assemblages of deglaciated lowland terrains. Ice-proximal and ice-contact depocenters provide important information on the former locations of glacier and ice sheet margins where they oscillated in proglacial lakes, and comprise a spatial and temporal continuum of subaqueous outwash fans, ice-contact deltas, and subaqueous (De Geer) moraines. These ice-proximal

and ice-contact features are distinct from the topset/foreset/bottomset-bedded Gilbert-, Salisbury-, and Hjulstrom-type glacier-fed deltas in that (a) they occur in physiographic settings where the only plausible source of sediment and water is a former glacier margin and (b) they contain a wide range of interdigitated deposits, including subglacial tills and glacio-tectonites, subaqueous outwash gravels and sands, and cohesive to cohesionless debris flow diamictos. Distal sedimentation is evident in iceberg-rafted debris and rhythmite sequences, often clearly recording seasonal variability in the influxes of fine-grained sediments in the form of varves. Evidence of secondary or syndepositional disturbance by glacier ice pushing and melt-out, iceberg and lake ice scouring, and dumping is widespread in the form of a whole range of deformation structures.

Micromorphology of Glacial Sediments

J F Hiemstra, Swansea University, Swansea, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

The dynamics and spatial variability of processes operating in glacial depositional environments may lead to sedimentary sequences that are highly diverse and complex, in terms of both composition and architecture. This makes the interpretation of many glacial sedimentary (paleo-)records challenging. Specific problems are associated with the interpretation of a range of glacial diamictos, which, although they are known to form in a multitude of ways, may appear identical to the naked eye (see [Glaciogenic Lithofacies](#); [Glaciomarine Sediments and Ice-Rafted Debris](#); [Tills](#)). Particularly where visible exposures of these sediments are limited, such as in sediment cores, it can be notoriously difficult or almost impossible to arrive at reliable interpretations when using conventional field sedimentological techniques alone.

Sometimes there is a need for more detailed information on sediments. For example, not being able to distinguish between subglacially (de)formed diamictos (basal tills) and ice-proximal glaciomarine diamictos in sedimentary records of formerly glaciated continental shelf areas will seriously affect the accuracy of paleo-grounding line reconstructions, which has detrimental effects on reconstructions of ice-sheet volumetric changes over time (see [Glaciomarine Sediments and Ice-Rafted Debris](#)).

In cases such as this, glacial sedimentologists have employed micromorphology. This technique, which has been the standard procedure for decades in rock mineralogical studies and paleopedology and which is starting to get established in other fields as well ([Menzies et al., 2010](#)), entails the analysis of up to 90 cm² thin sections under a transmitted-light petrographic microscope. Using magnifications commonly of 2× to 50×, texture, structure, and other microscale features of undisturbed, impregnated sediment samples can be analyzed in both plane- and cross (or circularly)- polarized light. Unlike other techniques, micromorphology allows for a detailed study of interrelations between sediment constituents, which has proved to be invaluable in genetic interpretations.

Sampling and Preparation of Thin Sections

If glacial sediments are unlithified, which is commonly the case for those of Quaternary age, they need to be sampled with great care. To ensure that disturbance is kept to a minimum and sedimentary and other primary structures are preserved, there is essentially a choice between two sampling methods, both of which can be quite elaborate. The first method is to carefully carve a block of material from an exposure or from a sediment core. The second method makes use of a special double-hinged, double-lidded tin (8 × 6 × 4 cm Kubišna-size, or 15 × 8 × 5 cm, so-called mammoth-size) and is

designed, and therefore particularly suitable, for brittle and non-cohesive materials. Sampling in this case involves the meticulous transfer of sediment into the tin by gently cutting and pushing the tin into the exposure. The tin is needed to support the loose material and to prevent the sample from disintegrating.

Unlike most rock specimens, which can be thin sectioned without preparation, unlithified sediment samples require impregnation before they can be cut, ground, and polished (e.g., [Murphy, 1986](#)). To prepare samples for impregnation, they need to be dried in order to remove all interstitial water. Normally, this involves 1 or 2 weeks of air- and oven-drying (at ~40 °C), but in exceptional cases, it may be necessary to expel excessive amounts of water by means of acetone replacement.

Impregnation is undertaken in a desiccator or sealed tank, in which a vacuum pressure of ~0.6 kPa is generated. The impregnation fluid mixture has crystic or epoxy resin as its most important component but also contains thinners and catalysts to enhance and speed up the process. Because at this stage the samples are still susceptible to disturbance, it is crucial that the fluid is applied in steadily increasing doses and that vacuum pressures are increased gradually in order to allow slow and optimal penetration of the resin into the sediment.

Curing of the impregnated samples normally takes between 4 and 8 weeks at room temperature and atmospheric pressure. Once hard, samples can be treated in much the same way as rock specimens and are ready for machine sawing, lapping, and grinding. In the final stage of producing the thin sections, slabs of impregnated samples are mounted on glass plates, ground, and polished to a thickness of ~30 μm, and covered with thin glass slips.

Thin Section Description

To help with communication between individual users of the technique in its application to glacial sediments, much effort has been put into standardizing the description of thin sections. Although still subject to modifications and refinements, a scheme has been in place since the 1980s, which is now recognized by most glacial micromorphologists. The nomenclature in this scheme, which was introduced by [van der Meer \(1987\)](#), is largely derived from the terminology used in soil micromorphology (cf. [Brewer, 1976](#); see [Soil Micromorphology](#)). Van der Meer recognized that many of the pedological terms, particularly those used to describe orientations and patterns in the silt and clay fraction (see below), would also be appropriate for the characterization of microscale features occurring in glacial sediments ([Figure 1](#)).

Micromorphological analyses of glacial sediments commonly involve observation, description, and interpretation of texture, structure, microfabric, and plasmic fabric (each discussed in detail in the following sections). Ideally, analyses should lead to the identification of microscale features that

Figure 1 Microstructures and plasmic fabric commonly found within glacial sediments. Reprinted from [Menzies J \(2000\)](#) Micromorphological analyses of microfabrics and microstructures indicative of deformation processes in glacial sediments. In: Maltman AJ, Hubbard B, and Hambrey MJ (eds.) *Deformation of Glacial Materials*, pp. 245–257. London: Geological Society. Special Publication 176. © 2000, with permission from The Geological Society.

indicate a certain depositional process or environment. The reliability of the genetic interpretation of glacial sediments is largely dependent upon how much evidence can be collected in support of this interpretation. It is important to realize in this respect that individual features are hardly ever diagnostic of a certain process or environment.

Textural Analysis

Textural analysis of thin sections involves the assessment (and measurement) of size, shape, distribution, and composition of particles larger (coarser) than $\sim 30\ \mu\text{m}$. In micromorphology, a distinction is made between particles $>\sim 30\ \mu\text{m}$ (defined as 'skeleton') and particles $<\sim 30\ \mu\text{m}$ (referred to as 'plasma'; [Figure 2\(a\)](#)). This threshold is not arbitrarily chosen but equals the thickness of an average thin section. This thickness determines the visual resolution of the technique: Because several layers of plasma may be contained within the thickness of a thin-sectioned sample, particles $<30\ \mu\text{m}$ cannot be examined individually.

While knowledge of the mineralogical composition may be important in establishing the provenance of a sediment, the size and shape of skeleton particles may hold rudimentary information about the processes of erosion, transport, and deposition. For example, observations of a large silt fraction and relatively rounded pebbles and sand grains in a glacial diamicton ([Figure 2\(b\)](#)) may be used to infer that the sediment under consideration has experienced a significant amount of subglacial modification during transport. This would suggest that processes such as abrasion, comminution, and attrition accounted for the production of silt-sized material and the associated edge rounding of the coarse fraction (see [Clast Form Analysis](#)).

Although advanced techniques such as spectrometry and diffraction analysis of fine-grained sediments can provide accurate information on mineralogical composition and grain-size distribution, respectively, neither technique can give a detailed insight into the spatial arrangement of individual constituents, or indeed resolve whether grains of certain size and/or composition are uniformly distributed, arranged in banded patterns or perhaps concentrated in clusters. Herein

Figure 2 (a) Distinction between skeleton (light particles $>30\ \mu\text{m}$) and plasma (darker matrix, particles $<30\ \mu\text{m}$) in a diamict (basal till) from the Netherlands. Plane-polarized light. (b) Diamict (basal till) from Germany showing plasma that is rich in silt (as reflected by its grainy appearance) and overall subrounded to some very well-rounded skeleton grains. Plane-polarized light. (c) Example of a cored diamict from the Greenland continental shelf showing intraclasts in different stages of development. Two well-rounded intraclasts occur next to features (both to the left and right) that seem to represent the early stages of their development. Plane-polarized light. (d) Intraclasts in a cored diamict recovered from the Antarctic continental shelf. In contrast to the situation in (c), the features here consist of a nucleus (a skeleton grain) and a casing of plasma material. This possibly indicates a different formation process, in which, as a result of rotation of individual skeleton grains, fine material is plastered onto their surfaces. Plane-polarized light.

lies the strength of microscopic texture analysis. Because thin section samples capture the undisturbed sediment, micromorphology allows the investigation of *in situ* particles and thus of the true small-scale sediment architecture. The importance of this is manifest in the study of sediments containing soft sediment intraclasts (or rip-up clasts) (Figure 2(c)–2(d)). Intraclasts, which occur quite commonly in glacial sediments, often indicate reworking of preexisting sediments, caused either by direct glacial action (see van der Meer, 1993) or by resedimentation, for example, as a debris flow (subaerial: see Menzies, 2000; subaqueous: Hiemstra, 2001; Kilfeather et al., 2010). The size, shape, composition, and position of intraclasts in the glacial sediment logically provide information on how and where preexisting sediments were incorporated and, more generally, on which mechanisms played a role in the formation of the glacial sediment as a whole. Such information is not disclosed through methods that make use of bulk samples.

Structural Analysis

In microscopic structural analysis, the arrangement and distribution of primary compound constituents, that is, the interrelations between aggregate particles, are investigated. Structures identified in thin sections of glacial sediment comprise features that result from depositional or deformational processes, or combinations thereof (see Menzies, 2000; van der Meer, 1993). Most glacial microstructures have a macroscopic equivalent. In other words, most can be regarded as smaller versions of known outcrop-scale features (see Figure 1; Glacitectonic Structures and Landforms; Glaciogenic Lithofacies).

Bedding and stratification are common depositional structures, which are often readily visible in sediments in the field. In

such cases, there is obviously no immediate need for micromorphological study. However, certain water-lain sediments are so finely or subtly laminated that investigation under the microscope is imperative, simply because such structures might otherwise go unnoticed, or would be incorrectly interpreted. For example, micromorphology allowed Palmer et al. (2010) to distinguish between sub-mm scale, annually deposited layers (varves) and other rhythmites in a Younger Dryas glaciolacustrine sequence, which enabled them to develop a high-resolution chronology for the area under investigation (see Glaciolacustrine).

Another example is given in Figure 3(a), which shows details of a very finely laminated fjord deposit. It comprises a series of mm-scale couplets consisting of a thin lamina of silt or fine sand (sometimes just one grain thick) that fines upward into a thicker lamina composed of silt and clay (cyclopels: see Hiemstra et al., 2004). This type of glaciomarine deposit is thought to result from suspension settling where turbid, fine particle-laden meltwater plumes interact with tidal marine currents (see Glaciomarine Sediments and Ice-Rafted Debris). Again, due to the subtlety of the structure, microscopic analysis was vital to fully appreciate the nature and history of the sediment.

When carrying out structural analysis of glacial sediments, it is important to realize that not all stratification (or lamination) is necessarily depositional in origin. Where a sequence of sediments is overridden by a glacier, it is quite common to find that deformation and glaciectonic processes produce so-called pseudostratification (pseudolamination) or transposed foliation (e.g., van der Wateren et al., 2000). In situations of low strain, it is possible that preexisting structures are retained or only modified to some degree (Figure 3(b)), so that occurring stratification is a primary feature, but where

Figure 3 (a) Glacimarine cyclopel sequence recovered from an Alaskan fjord (see text for explanation). Plane-polarized light. (b) Example of a glacimarine deposit from the Antarctic continental shelf in which preexisting stratification is largely preserved (with the exception of a flamelike structure on the right hand side of the image). This reflects a relatively minor disturbance in a low-strain situation. (c) Higher-strain situation in which stratification in the areas indicated was once connected (now separated as a result of discrete shearing: arrowed plane). Also note birefringence in the plasma, both within the shear plane and in the stratified parts (see below). Example from glacimarine fjord deposit, Alaska. Cross-polarized light. (d) Example of pseudo-lamination caused by simple shear. Note streamlined, boudinaged silty laminae. Example from Alaska: glacimarine fjord deposit in plane-polarized light. (e) Disrupted stratification in part of the CIROS-1 sediment core (Antarctica). Brittle deformation: single joint and two faults. Plane-polarized light. (f) Example from a glacitectedonized glacimarine deposit from Spitsbergen showing complex ductile and brittle deformation comprising superimposed joints, faults and conjugate shears (as reflected by planar fractures), and discrete zones of plasmic fabric (arrows). Note that the original, primary stratification can still be discerned. Cross-polarized light.

higher strain occurs, any stratification present is more likely to have developed through attenuation of inhomogeneities in the deforming (subglacial traction) layer of sediment or glaciectonite (Figure 3(c); cf. Benn and Evans, 1996; Evans et al., 2006; see Tills). Such inhomogeneities are commonly introduced into the deforming layer from the immobile sediment substrate below. Once incorporated, inhomogeneities may be boudinaged, that is, develop into sausagelike forms, and eventually be stretched into streamlined lenses and tectonic laminae (Figure 3(d)). Alternatively, incorporations may be folded and rotated, which could lead to the formation of rounded intraclasts (see above).

Clearly, the type of (micro)structures that will develop is largely dependent on the type and nature of the deformation. In glacier submarginal or proglacial settings, sediments are generally compressed, which leads to folding, whereas in subglacial

settings, extensional regimes are prevalent, which means that attenuation is more common. It should be noted, however, that because glacial sediment may undergo several cycles of extension and compression, resultant structural patterns can be extremely complex and may comprise various superimposed features. Microscopic analysis of such deformed sediments greatly facilitates the unraveling of their history and thus aid the interpretation of glacial sequences (Phillips and Auton, 2000; Phillips et al., 2007; Figure 4). Superimposed structures not only reflect consecutive stages of extensional and compressive deformation but may also reflect changes in deformation style and intensity. The latter changes are controlled, for example, by clay and water content (see Phillips et al., 2007; van der Meer et al., 2003), which determine whether a sediment responds in essentially a brittle or a ductile fashion, in other words, whether structures such as fissility, joints, and faults or

Figure 4 Detailed cartoon of a thin section from Strathspey, Scotland, showing a range of microstructures developed in a laminated fine-grained deposit. Note the complex structural geometry, indicating polyphase deformation. Reworking of primary lamination involved folding, thrusting, and faulting, both normal and reverse. Reprinted from Phillips ER and Auton CA (2000) Micromorphological evidence for polyphase deformation of glaciolacustrine sediments from Strathspey, Scotland. In: Maltman AJ, Hubbard B, and Hambrey MJ (eds.) *Deformation of Glacial Materials*, pp. 279–292. London: Geological Society. Special Publication 176. © 2000, with permission from The Geological Society.

crenulations, folds, and pressure shadows (areas of low strain, associated with flow around rigid objects) dominate (Figures 1 and 3(e)–3(f); see Menzies, 2000).

Where sediments are strained to an extent that all primary sedimentary features are erased and all inhomogeneities are stretched or reworked beyond macroscopic recognition, micromorphology can be indispensable. In such cases, very subtle arrangements of skeleton grains often present the only clues for unraveling a sediment's history. Seemingly insignificant microstructures such as lineaments and turbates, that is, linear, respectively circular arrangements of elongated skeleton grains (Figure 5(a) and 5(b)), have been shown to reflect particle reorientations in response to simple shear (Hiemstra and Rijdsdijk, 2003) and are now quite confidently used to distinguish between deformed and undeformed glacial sediments.

Microfabric Analysis

The occurrence of turbates and lineaments in deformed glacial sediments clearly illustrates that individual grains tend to readjust their positions when subjected to stresses (cf. Larsen et al., 2007). This is the essence of microfabric analysis, which involves the examination of the arrangement and orientation of particles at a microscopic scale. The objective is to reconstruct stress vectors at the time of formation and thus to learn about the depositional environment. Although size limits have never been defined exactly, it is common practice in microfabric analysis of thin sections to examine particles ~100 to ~6 mm in size. The lower limit is chiefly determined by resolution, whereas the upper limit is conveniently set to complement

macrofabric analysis as carried out in the field (see Till Fabric Analysis).

Traditionally, microfabric data have been used to infer former ice flow directions from subglacial sediments (e.g., Evenson, 1971). The idea is that fine particles become aligned with their long axes predominantly parallel to the ice flow while displaying dips in upglacier directions (cf. Thomason and Iverson, 2006). However, it has also been suggested that certain particles may attain positions transverse, that is, perpendicular, to ice flow, lending support to the idea that apart from depositional and deformational processes, the shape and size of particles may also have some control over how they become oriented (Carr and Rose, 2003; Kjør and Krüger, 1998; Figure 6).

In contrast to macrofabric analyses (see Till Fabric Analysis), where clasts can be removed from a sediment exposure to check the degree of elongation and their dimensions and to establish accurately their orientation and dip (or compass bearing and plunge), microfabric measurements have to be taken either directly from a two-dimensional (2D) thin section or from a projected image, which means that orientations of perceived elongated particles are always apparent rather than true. The most common solution to this problem is to produce two or three mutually orthogonal thin sections, perform measurements in all planes, and work out the true microfabric characteristics mathematically (Evenson, 1971).

This method is quite laborious, however, and prone to subjective bias in that the operator has to select the elongated particles. In fact, such limitations have probably been the reason why microfabric analysis is not yet a standard procedure in glacial micromorphology. However, the introduction of

Figure 5 (a) Example of a turbate structure in which the long axes of fine grains are positioned parallel to the surface of the large grain in the center of the image. This structure suggests that the large grain, under influence of shear stresses, has performed a rotation, dragging the fines in its vicinity with it and forcing them to realign. Sample from the Antarctic continental shelf. Plane-polarized light. (b) Example of a lineament structure, which consists of at least five elongated grains which have their long axes in the same (shear) plane. Note that the larger grain on the left has a turbate structure around it, which illustrates the close association between the two structures in terms of genesis. Sample from the Antarctic continental shelf. Plane-polarized light.

Figure 6 Fabric rose diagrams of three glacial till samples from Balglass, Scotland. Plotted are the 2D orientations of particles in four textural classes. The inferred local ice flow direction is indicated by the red arrow. Carr and Rose (2003) suggested that both stress history and size class may influence particle orientation patterns. Note both transverse and parallel signals. automated (i.e., computer-based) analyses has shown potential in facilitating the study of microfabric anisotropy. Derbyshire et al. (1992), for example, introduced the use of Fourier series, and more recently, Stroeven et al. (2005) employed stereological principles demonstrating that the time efficiency and objectivity of the method can be improved dramatically. Stereology, by definition, is a sampling theory for

Figure 7 Directed secants analysis. (a) Circled area in a thin section image is subjected to systematic line scanning, which entails the counting of the number of intersections between the secants and the particle traces for each 10° of rotation. (b) The situations at $\theta = 0^\circ$ and $\theta = 90^\circ$ are illustrated. (c) A schematic rose of intersection densities, which is used to identify the preferred fabric orientation of the sample under consideration. Reprinted from Stroeven AP, Stroeven P, and van der Meer JJM (2005) Microfabric analysis by manual and automated stereological procedures: A methodological approach to Antarctic tillite. *Sedimentology* 52: 219–233. © 2005, with permission from Wiley-Blackwell and the International Association of Sedimentologists.

populations having a geometric structure and, in its application to microfabric, allows for the derivation of preferred orientations from measurements on particles in two projection planes (i.e., two orthogonal thin sections). In practice, the orthogonal set of thin sections is subjected to directed secant analysis (Figure 7), in which the number of intersections

between particle traces and a rotating line system is determined. With this information, 3D preferred orientations of the particles can be easily calculated using a set of straightforward trigonometric relations (Stroeve et al., 2005).

Plasmic Fabric Analysis

Plasmic fabric refers to the arrangement of particles $< \sim 30 \mu\text{m}$. Although resolution limitations preclude the study of individual particles (see above), certain zones or domains consisting

of aligned particles may show interference colors under cross- or circularly polarized light, which allows preferred orientations to be studied even at plasma level. As with larger skeleton grains, particles in the plasma (notably clay platelets) tend to accommodate stresses applied during deposition or deformation by (re)adjusting their positions so that plasmic fabric can be used in much the same way as microfabric.

The interference color of the plasma depends on the thickness of the thin section and an optical property called birefringence, which is defined as the difference between the two

Figure 8 (a) Image of a till recovered from the Antarctic continental shelf showing a band of masepic plasmic fabric. Note that within the indicated zone, birefringence is high, whereas outside, the plasma shows no preferred orientation. Cross-polarized light. (b) Light grain in the center of the image shows a well-defined, thick halo of skelsepic plasmic fabric. Note that the dark grain to the left shows a zone of skelsepic plasmic fabric which is very much thinner. This suggests that this type of birefringence may result from different processes (see text). Cross-polarized light. (c) Pervasive type of masepic plasmic fabric conforming to the lamination in a fine-grained diamicton recovered from the Antarctic continental shelf. Cross-polarized light. (d) Another example from the Antarctic continental shelf showing a shear zone (from lower left to upper right of the image) with thin, continuous unistrial plasmic fabric representing discrete, anastomosing shear planes. Cross-polarized light. Compare shear zone geometry with patterns in [Figure 10](#).

Figure 9 Conceptual model illustrating the strain signature in sediments affected by (1) subaqueous gravity-driven sliding and (2) subglacial deformation. [Hiemstra et al. \(2004\)](#) observed reversed trends in deformation profiles and used these to distinguish between different types of deformation. Note theoretical shear zone configuration (conjugate shear planes in central columns) and black strain markers. refractive indices of the anisotropic domain ([Cribble and Hall, 1992](#); [Figure 8\(a\)](#)). Not only is the intensity or brightness of the colors is dependent on the degree of particle orientation, but it is also controlled by the orientation of the thin section relative to these particle orientations. Maximum birefringence is displayed only if both the maximum and minimum refractive indices of a particular anisotropic domain lie within the plane of the thin section.

Following [Brewer's \(1976\)](#) terminology for microscopic phenomena in soils (see above), many glacial micromorphologists employ terms such as skelsepic, unistrial, and masepic plasmic fabric to describe birefringence patterns (see also [Figure 1](#)). Skelsepic plasmic fabric is defined as plasma separations occurring subcutanically around skeleton grains, that is, where the birefringence occurs in haloes parallel to the surface of the grains ([Figure 8\(b\)](#)). There are at least three explanations for this type of plasmic fabric. The first is that clay platelets become realigned due to torque-generated rotational movements of individual skeleton grains within the plasma (e.g., [van der Meer, 1993](#)), an idea that finds support in the frequent observations of their concurrence with turbate structures (e.g., [Hiemstra and Rijdsdijk, 2003](#)). The second explanation is that skelsepic plasmic fabric results from translocation of clays through pore-water movements in simple shear-induced dilating sediment ([Menzies, 2000](#)), while a third proposes swelling of clays during repeated drying–wetting cycles as a possible explanation (e.g., [Jim, 1990](#)). Assuming that all three explanations are equally plausible, it would mean that both anisotropic and isotropic shear regimes could be responsible for the alignments and that, although quite common in, for example, subglacially deformed tills, skelsepic plasmic fabrics are by no means diagnostic of this type of sediment.

Figure 11 Application of a multispectral classification algorithm to identify the main components of a cross-polarized image of a glacial sediment (unprocessed image (a)). (b) The same image after the first stage of classification. Different shades of gray represent objects of similar appearance. (c) The image after the next stage clearly highlights fractures (white), plasma (dark gray), skeleton grains (lighter shades of gray), and unknown matter (black). (d) The image through a birefringent plasma mask (based on differences in red and green values for individual pixels), allowing identification of plasmic fabric patterns. Reprinted from [Zaniewski K, van der Meer JJM \(2005\)](#) Quantification of plasmic fabric through image analysis. *Catena* 63(1): 109–127, © 2005, with permission from Elsevier.

In fact, this applies to all plasmic fabric types. To date, not one birefringence pattern has been identified that could unequivocally be related to a singular depositional or deformational process. Nevertheless, plasmic fabric analysis may be regarded as one of the more powerful tools in micromorphology. Particularly in deformed glacial sediments, the occurrence of so-called striated birefringence usually provides crucial information about how strain evolved in response to progressive simple shear. Types such as masepic plasmic fabric and its more continuous variant, unistrial plasmic fabric, which show streaks or lines of uniformly oriented plasma (**Figures 1 and 8(c) and 8(d)**), can be analyzed in terms of geometry and lead to very specific information on the type and direction of shear, even if the signature can be studied only in one single thin section plane (**Hiemstra et al., 2004**; see **Figure 9**). Noteworthy in this respect is the application of kinematic principles to striated birefringence analysis (**van der Wateren et al., 2000**). This approach makes use of analogies with deformation structures found in low-grade metamorphic rocks (see **Passchier and Trouw, 1996**). **Van der Wateren et al. (2000)** explained how deformed glacial sediments may reveal plasmic fabrics that are very similar to Riedel shear patterns and ductile shear band cleavages in, for example, mylonites, a similarity which thus allows for the reconstruction of finite strain ellipsoids and for drawing inferences with regard to shear type, direction, and geometry (**Figure 10**; cf. **Larsen et al., 2006; 2007; Thomason and Iverson, 2006**).

It should be noted that, as with microfabric analysis, there is obviously an element of bias involved in plasmic fabric analysis. It is not unlikely that the relative strength of plasmic fabric – potentially useful in the quantification of strain – is rated differently by different observers, and secondly, it is quite possible that subtle birefringence patterns go undetected due to human eyesight limitations. Again, the use of image analysis techniques seems to be the way forward. Through the use of multispectral image classification, for example (see **Figure 11**), **Zaniewski and van der Meer (2005)** made an attempt to control the subjectivity in plasmic fabric analysis. Although the authors themselves state that the quantification of birefringence is still very much in its infancy, there seems to be merit in automated approaches.

Recent and Future Developments in Microscopic Studies

In recent years, improvements to the technique of micromorphology have involved developments in the areas of objectivity and efficiency. These were mainly achieved through automated, that is, computer-assisted analyses of thin section samples (as described earlier: stereology – microfabric, image analysis – plasmic fabric). However, there have also been successful attempts to make micromorphology less ‘descriptive,’ less subjective, and more systematic through ‘manual’ quantification (counting and calculation of microstructure density: **Larsen et al., 2006, 2007; Reinardy et al., 2011**) and the use of multiple observers to reduce or overcome observer bias (**Larsen et al., 2007**).

With regard to observer bias, it is worth noting that there is an increasing awareness that psychology may be more significant in thin section analysis than previously thought. **Leighton et al. (in press)** are looking into the possibility that human perception and identification of patterns (such as turbate microstructures) are at least partially based upon (and controlled by) previous experience and conditioning of the brain.

Another interesting development is, and has been, that of the introduction of microtomography. Although so far few publications have reported on its application to glacial sediments (**Kilfeather and van der Meer, 2008; Tarplee et al., 2011**), the technique may be expected to complement micromorphology in the future, thus allowing for visualization and reconstruction of 3D phenomena on the basis of 2D information.

Microtomography is a technique that is similar to CAT scan imaging as used in medicine but achieves a much higher resolution of $\sim 2\ \mu\text{m}$. It involves exposing natural, untreated sediment samples to high-power x-radiation and obtaining projected images (radiographs) of these samples in planes that are perpendicular to the x-ray beam direction. By rotating individual samples through small angular increments, series of several hundred of such radiograms are acquired, which via mathematical algorithms can be converted into 3D images (**Figure 12**).

Figure 12 x-Ray computed microtomography. (a) Example of a radiograph of a cylindrical till sample; a total of 400 radiographs cover the entire sample (rotating through 360° at steps of 0.9°). (b) Two examples of reconstructed slices through the cylinder; approximately 1000 of these are reconstructed along the vertical sample axis. (c) Examples of reconstructed 3D blocks of part of the cylinder with pores spaces highlighted. Image courtesy of J.J.M. van der Meer.

Tomographic images are composed of millions of volumetric elements (voxels), each carrying a value representing the amount of x-radiation absorbed. The 3D images can be sliced at any given angle to show cross sections, and every single image – both 2D and 3D – can obviously be subjected to a range of image analysis techniques allowing for detailed investigation of, for example, internal structures, reflected in, for example, fabrics or pore spaces (Figure 12).

Subglacial Processes

The observations and data available in the existing literature on till sedimentology allow us to identify four main processes of till production in the subglacial environment, including sliding/lodgement, melt-out, deformation, and cavity filling. Additionally, the process of ploughing and the concept of a lodgement–deformation continuum can potentially produce a recognizable till end member.

Subglacial Sliding and Lodgement

Subglacial sliding over a rigid bed is well documented, and soft-bed sliding has been proposed to explain the characteristics of certain till sequences (e.g., Brown et al., 1987; Clark and Hansel, 1989; Piotrowski and Tulaczyk, 1999). This involves glacier bed decoupling due to increased basal water pressures, which prevent the transmission of stress to the soft substrate (Fischer and Clarke, 1997; Fuller and Murray, 2000). Spatial variability in the intensity of sliding may explain the characteristics of certain tills, as proposed by Piotrowski and Kraus (1997), who further suggest that the glacier bed is a mosaic of sliding bed conditions and deforming patches or spots (Figure 1). This is supported by Thorsteinsson and Raymond (2000), who suggest that sliding must be the dominant mechanism of basal motion beneath an ice stream, as opposed to till shearing, unless there is either adhesion of till to the ice sole, short-scale roughness at the ice–till interface, or internal slip boundaries in the till.

Lodgement is defined as the plastering of glacial debris from the base of a sliding glacier on to a rigid or semirigid bed by pressure melting and/or other mechanical processes (Dreimanis, 1989). This includes the lodgement of debris-rich basal ice masses as well as individual clasts (Figure 2). The lodging of preexisting till masses gives rise to the term ‘deformed lodgement till’ (Dowdeswell and Sharp, 1986). The lodgement process preferentially deposits larger clasts while finer grain sizes remain in motion due to deformation (see section ‘Lodgement–Deformation Continuum’). This poses problems when explaining thick fine-grained till sequences due to lodgement. Consequently, a range of contemporaneous subglacial processes have been proposed for temperate glaciers in order to explain the accumulation of thick tills, including simultaneous lodging, ploughing, and shear deformation at the glacier bed, whereby large particles lodge first and smaller particles remain in traction until strain rates fall (Benn, 1994; Boulton and Hindmarsh, 1987; Boulton et al., 1974; Evans and Twigg, 2002; Kruger, 1994).

Subglacial Melt-Out

Subglacial melt-out is the slow and passive release of sediment from debris-rich stagnant basal glacier ice. The process is

defined by theoretical postulates based upon interpretations of ancient tills (e.g., Haldorsen and Shaw, 1982; Munro-Stasiuk, 2000; Piotrowski et al., 2001; Shaw, 1979, 1982, 1983; Figure 3), although support has been provided by observations at modern glacier snouts where basal tills have apparently been released from overlying debris-rich ice (Boulton, 1971; Lawson, 1979a,b; Shaw, 1982). High debris concentrations in melting ice result in low thaw consolidation ratios, and, if drainage is efficient, delicate englacial structures may be preserved (e.g., Carlson, 2004). However, the ideal conditions for melt-out till preservation are probably rare, because poor drainage and high ice contents will produce high porewater pressures in the accumulating melt-out sequence thereby initiating failure, remobilization, and dewatering (Paul and Eyles, 1990). Additionally, the paleoglaciological requirements for melt-out till production often appear unrealistic. For example, Boulton (1996) points out that in order to produce a melt-out till sequence in excess of 10 m (a commonly reported thickness) would require more than 100 m of debris-rich ice of average debris concentration, far in excess of any present-day basal ice sequences.

Subglacial Deformation

The subglacial deformation of sediments and soft rocks accounts for some of the forward motion of many glaciers (Alley, 1989a,b; Alley et al., 1986, 1987a,b; Boulton and Hindmarsh, 1987; Clarke, 1987; Humphrey et al., 1993). The Icelandic subglacial experiment reported by Boulton (1979), Boulton and Hindmarsh (1987), and Boulton and Dobbie (1998) and the high-resolution seismic surveys beneath Ice Stream B, Antarctica (Blankenship et al., 1986, 1987) are benchmark studies providing the most compelling case for substrate deformation. The Icelandic experiment revealed a convex-upward displacement curve in the till, marked by the displacement of strain markers, which was interpreted as viscous response to applied stress (Figure 4). Further studies at the base of modern glaciers have confirmed the role of deforming beds and highlighted the role of fluctuating porewater pressures in controlling sliding versus deformation temporally (e.g., Blake et al., 1992; Fischer et al., 1999, 2001; Iverson, 1999; Iverson et al., 1994, 1995, 1999). Laboratory experiments (e.g., Iverson and Iverson, 2001; Watts and Carr, 2002) have reproduced convex-upward displacement curves through plastic failure of till, with failure taking place along discrete planes, implying that such curves do not necessarily indicate a viscous rheology. The consensus on the rheological behavior of subglacial tills is that they behave plastically but undergo spatially distributed deformation, thereby producing a pattern of displacement that resembles a viscous material (Fowler, 2002, 2003).

Some stratified sediment bodies found in association with basal tills are related to subglacial drainage during till deposition, based upon theoretical reconstructions of subglacial

Figure 1 Conceptual model of the subglacial deforming/sliding bed mosaic proposed by Piotrowski and Kraus (1997). The model compares subglacial shear stress (τ) with sediment shear strength (τ_f). The shear stress is lower than the sediment shear strength wherever high basal water pressures cause ice–bed decoupling. Elsewhere the bed develops deforming spots.

hydrological conditions (Figure 5). Walder and Fowler (1994) suggest that drainage beneath a soft-bedded glacier occurs in a series of braided canals (Ng, 2000) at the ice–till interface when discharges are too large to be evacuated through the bed. This leads to ice–bed separation, thereby temporarily inducing sliding and shutting down till deformation/lodgement. Drainage of meltwater through a till, particularly one that is deforming, can occur either by Darcian porewater flow or by pipe flow. Many subglacial tills also contain vertical dykes or injection structures composed of nontill sediment. Such features are interpreted as the products of meltwater movement through till due to subglacial water escape (van der Meer et al., 1999) or hydrofracture fills relating to the burst out of pressurized groundwater (Boulton and Caban, 1995; Mandl and Harkness, 1987; Rijdsdijk et al., 1999).

Lee-Side Cavity Filling

The infilling of lee-side cavities, as observed at the irregular beds of modern glaciers with rigid substrates, involves a range of processes that interact with all of the above sediment emplacement mechanisms (Boulton, 1982; Boulton and Paul, 1976; Vivian, 1975). This includes slurring, expulsion and fall, decollement, and debris-rich ice ‘curl’ detachment and fluvial inwashing (Figure 6). The cavity-fill deposits are often heavily overprinted by the sedimentary and structural signatures of other till-forming processes due to the recoupling of glacier ice with its bed. Hence, Boulton (1971) regards cavity filling as essential to the smoothing of the irregularities in the bed of a glacier depositing till by other subglacial traction/deposition processes.

Reproduced from Benn DI and Evans DJA (1996) *The interpretation and classification of subglacially deformed materials. Quaternary Science Reviews* 15: 23–52.

Subglacial Ploughing

Similar to the ploughing of boulders through subglacial sediment (e.g., Brown et al., 1987; Clark and Hansel, 1989; Weertman, 1964), it has been hypothesized that the grooved base of a glacier can plough through soft substrates (Clark et al., 2003; Tulaczyk et al., 2001). The ice ploughing model has been proposed because previous models of subglacial deformation were increasingly unable to explain: (i) the results of laboratory experiments on subglacial tills, in which a Coulomb-plastic rheology has been demonstrated; and (ii) field measurements in which basal sliding and/or shallow deformation is apparent. Ploughing involves disturbance and transportation of subglacial till up to a few meters thick by the keels in a sliding, bumpy glacier sole. Tulaczyk et al. (2001) propose an analogy with the fault gouge model of Eyles and Boyce (1998) in which the sliding ice base acts as the rigid upper fault plate. The asperities in the fault plate, whether clasts or bumps/keels in the ice sole, plough through the soft substrate, generating the deformable till (fault gouge layer) above the underlying, rigid strata (lower fault plate).

Lodgement–Deformation Continuum

The spatial and temporal variability in ice–bed coupling due to changes in pressure distribution of the basal water system leads to variability in basal motion mechanics (Fischer and Clarke, 2001; Fischer et al., 1999). This gives rise to a patchwork of sticky spots and areas of stick–slip sliding, the extent of which vary in response to changes in the basal meltwater pressure. Such processes have been measured by Boulton

Figure 6 Schematic diagrams representing observations of sediment accumulation in subglacial cavities. Reproduced from Boulton GS (1982) *Subglacial processes and the development of glacial bedforms*. In: Davidson-Arnott R, Nickling W, and Fahey BD (eds.) *Research in Glacial, Glacio-fluvial and Glacio-lacustrine Systems*, pp. 1–31. Norwich: Geo Books.

Figure 7 Schematic reconstruction of the concept of the stable/deforming subglacial bed mosaic concept of Piotrowski JA, Larsen NK, Frank FW, and Junge W (2004) Reflections on soft subglacial beds as a mosaic of deforming and stable spots. *Quaternary Science Reviews* 23: 993–1000. The position of the deforming spots on the bed changes spatially and temporally, producing overprinted deformation signatures in the subglacial material.

et al. (2001) who also document changes from sliding to deformation at specific locations. This can be reconciled with the spatial variability in sliding intensity proposed by Piotrowski and Kraus (1997) and the subglacial mosaic model of sliding and deformation proposed by Piotrowski et al. (1997) (Figure 7). Similarly, Lian and Hicock (2000) propose a change from lodgement to deformation to explain complex tills in the North American Cordillera.

Based upon the discussion presented above, it is clear that a combination of till transport and deposition processes is most likely in subglacial environments. A unifying model for subglacial till production must recognize the various processes observed in modern glacier systems and acknowledge the temporal and spatial variability in those processes at the glacier bed.

Figure 8 Highly fissile, compacted diamicton with bullet-shaped and faceted clasts, typical of subglacial lodgement till.

Subglacial Till Types

There are seven till types, some often found in association with stratified sediments, which have been proposed as the products of the processes discussed above, that is, lodgement till, melt-out till, sliding bed deposits, glacioteconite, communiton till, deformation till, and lee-side cavity fills. The geological signature of each of these till types is now reviewed in turn.

Lodgement Till

Lodgement till is defined as “sediment deposited by plastering of glacial debris from a sliding glacier sole due to the combined effects of pressure melting and frictional drag” (Chamberlin, 1895). It is either massive in appearance at outcrop or contains numerous subhorizontal joints which can be polished or slickensided and striated, indicating that they may be shear planes (Benn, 1994; Boulton, 1970; Figure 8). Grain-size characteristics and clast forms reflect the processes of grain crushing and

abrasion. Abundant stoss-and-lee forms are produced when clasts become lodged and then abraded and plucked, much like a miniature *roche moutonnée* (Boulton, 1978; Kruger, 1979, 1984, 1994; Sharp, 1982), although similar forms may be produced within deforming layers (Benn and Evans, 1996). Lodgement may produce clast clusters or pavements where lodged clasts cause the retardation of further debris (Boulton, 1975, 1982), although such pavements have also been interpreted as deformation products. Lodgement may also take place on a deformable bed and may be significant in the production of deformation tills whereby large clasts in the glacier sole plough through the substrate until their forward momentum is arrested; hence, the identification of a lodgement–deformation continuum. Modern lodgement tills clearly contain lodged particles with strong macrofabrics recording ice flow direction, ploughed particles, and shearing/deforming sediment (e.g., Benn, 1994; Kruger, 1994), the relative importance of lodgement and deformation in some instances varying with clast size

(e.g., Benn, 1994, 1995; Benn and Evans, 1996). Some significant problems of nomenclature have arisen from such observations (e.g., Ruszczyńska-Szenajch, 2001) and it is unclear what proportion of a subglacial diamicton must be lodged before it can be classified as a lodgement till rather than a deformation till. Unless some significant deformation and stacking of subglacial sediment occurs, it is difficult to envisage how the lodgement process *sensu stricto* can produce thick till sequences.

Subglacial Melt-Out Till

Melt-out till is defined as “sediment released by the melting of stagnant or slowly moving debris-rich glacier ice, and directly deposited without subsequent transport or deformation” (Benn and Evans, 1998). Few process studies have demonstrated melt-out till production (e.g., Ham and Mickelson, 1994; Lawson, 1979a,b, 1981), and consequently the characteristics of melt-out tills are largely based upon inferences from the geological record (e.g., Boulton, 1970, 1971; Haldorsen and Shaw, 1982; Mickelson, 1973; Ronnert and Mickelson, 1992; Shaw, 1982). Subglacial melt-out tills should inherit the foliation and structure of the parent ice but this is usually modified during the melt-out process, the least disturbed deposits being the product of sublimation (hence sublimation till of Shaw, 1977, 1988). Proposed examples of subglacial melt-out till display discontinuous and contorted layers and lenses; textural and compositional banding with indistinct contacts and internal flow structures; and undeformed, intratill soft sediment, or soft bedrock rafts (Lawson, 1979a,b; Shaw, 1979, 1982, 1983; Figure 9). Strong clast macrofabrics, recording the former glacier flow direction, are also regarded as diagnostic criteria (Lawson, 1979a,b). However, problems in differentiating ancient melt-out tills from the products of other subglacial processes persist, particularly where foliated or banded tills, interpreted by some as melt-out till (e.g., Clayton et al., 1989; Munro-Stasiuk, 2000; Ronnert and Mickelson, 1992), are regarded by others as the products of deformation (e.g., Alley, 1991; Boulton, 1996; Evans, 2000a).

Subglacial Sliding Bed Deposits

Occurrences of sub till and intratill stratified sediments have been interpreted as indicative of sliding glacier bed conditions (Figure 10), because they document deposition by a water film at the ice–bed interface (Piotrowski and Kraus, 1997; Piotrowski and Tulaczyk, 1999). This implies also that the tills found in association with the stratified units must be deposited by passive melt-out or that the stratified units record water films at the base of sliding tills (Hindmarsh, 1996). Undeformed, sub till stratified sediments are often found juxtaposed with deformed or mixed till–substrate contacts, suggesting that deforming layers and subglacial channels can coexist (Alley, 1992) and supporting the notion of a sliding and deforming glacier bed mosaic (Piotrowski and Kraus, 1997; Piotrowski et al., 2001, 2002) involving temporally varying sticky spots (Fischer and Clarke, 2001; Fischer et al., 1999). Therefore, till characteristics may change over short distances depending upon the predominant process at the time the glacial depositional system shut down. Stratified

(b)

(c)

Figure 9 Characteristic features of melt-out till: (a) soft sediment intratill lens, Alberta, Canada; (b) idealized vertical profile of typical features of proposed melt-out at the Matanuska Glacier, Alaska (reproduced from Lawson DE (1981) Distinguishing characteristics of diamictons at the margin of the Matanuska Glacier, Alaska. *Annals of Glaciology* 2: 78–84) – ‘a’ structureless pebbly, sandy silt; ‘b’ discontinuous laminae, stratified lenses, and pods of texturally distinct sediment in massive pebbly silt; ‘c’ layers of texturally, compositionally or color-contrasted sediment. Laminae or layers may drape over large clasts.

Figure 10 Examples of proposed ice–bed separation features. All features lack significant deformation and sand layers are interpreted as the product of thin water films at the ice–bed interface: (a) subhorizontal, often slickensided fissures, in places filled with syndepositional sorted sediments; (b) subhorizontal fissures (upper part) and thin stringers of sorted sediments interbedded with till matrix (lower part); (c) horizontally stratified till consisting of millimeter-thick sand layers intercalated with till matrix; (d) single horizontal stringer of stratified sand in till matrix. Reproduced from Piotrowski JA and Tulaczyk S (1999) Subglacial conditions under the last ice sheet in northwest Germany: Ice-bed separation and enhanced basal sliding? *Quaternary Science Reviews* 18: 737–751, with kind permission from J. Piotrowski.

sediments may also be interbedded with tills squirted into channels from nearby deforming layers or may record periods of subglacial meltwater sheetflow between phases of deformation till accretion. Further complications may then arise when such interbedded sequences are glacioteconized during later periods of ice–bed coupling (e.g., Boyce and Eyles, 2000; Evans et al., 1995; Eyles et al., 1982; Figure 11).

Glacioteconite

Glacioteconite (Banham, 1977; Pedersen, 1988) is defined as “rock or sediment that has been deformed by subglacial shearing (deformation) but retains some of the structural characteristics of the parent material” (Benn and Evans, 1998). The appearance of a glacioteconite reflects the nature of the parent material and its strain history, displaying evidence of either brittle or ductile deformation or a combination of the two processes (Figure 12). Inhomogeneous materials can display extremely complex deformation structures due to the variable response of individual sedimentary beds of differing rheology (e.g., Benn and Evans, 1996; Evans, 2000b; Evans et al., 1998; Hicock, 1992; Hicock and Fuller, 1995; Ó Cofaigh and Evans, 2001; Phillips et al., 2002). Benn and Evans (1996) identify Type A glacioteconites, which show evidence of penetrative deformation, and Type B glacioteconites, which have

undergone nonpenetrative deformation. The pervasive deformation of Type A glacioteconites to high cumulative strains can produce a tectonic foliation where primary structures are attenuated and rotated toward parallelism with the direction of shear (e.g., Hart, 1995; Hart and Boulton, 1991; Hart and Roberts, 1994) or transposed due to the imposition of a new foliation. Type B glacioteconites are produced by pervasive ductile deformation to small total cumulative strains and consequently, the predeformational sedimentary structures are still recognizable.

Comminution Till

Comminution till is defined as a “very dense till that appears to have been formed by abrasion of bedrock and the crushing of detritus dragged along underneath the ice, accompanied by a mixing process that results in the incorporation of rock powder produced by abrasion at the till–rock interface into the overlying glacial load” (Elson, 1988). Bedrock crushing and pulverizing reduces pore spaces and increases interparticle contacts, resulting in a grain size similar to that produced by industrial crushing and grinding (Benn and Evans, 1998; Elson, 1988). Grain crushing, fracturing, and attrition in the subglacial environment has been widely recognized (e.g., Boulton et al., 1974; Haldorsen, 1981; Hiemstra and van der Meer, 1997; Hooke

Figure 11 A model of till and interbed deposition (reproduced from Boyce *JI* and Eyles *N* (2000) Architectural element analysis applied to glacial deposits: Internal geometry of a late Pleistocene till sheet, Ontario, Canada. *Bulletin of the Geological Society of America* 112: 98–118): (a) the conceptual model involving: ‘a’ erosion and deformation of preexisting unlithified sediments to form drumlinized surface; ‘b’ conformable aggradation of deformation tills on drumlinized surface; ‘c’ subglacial fluvial reworking of diamictic till to form sheet-like interbeds and boulder pavements; ‘d’ continued aggradation of deformation tills and stratified interbeds; (b) schematic illustration of architectural element types with typical bounding surfaces as represented by interbeds. DE, diamict element, where tabular beds separated by planar to gently undulating bounding surfaces with occasional clast pavements are deposited by aggradation of deformation till; I = interbeds comprising coarse (I-c) and fine (I-f) ice-bed separation deposits; DZ, deformed zone comprising glacially deformed preexisting strata. Numbers in black dots refer to bounding surfaces whereby sixth-order surface, mappable stratigraphic unit; fifth-order surface, laterally continuous erosion surface; fourth-order surface, boundary between architectural elements; third-order surface, laterally discontinuous minor erosion surface; second-order surface, boundary defining dissimilar lithofacies; first-order surface, boundary separating similar lithofacies; and zero-order surface, laminae (see Boyce and Eyles, 2000 for details).

and Iverson, 1995; Yi Chaolu, 1997) but the production of thick comminution tills is most likely assisted by the displacement of relatively soft and/or heavily fractured bedrock slabs or thrust slices prior to crushing and disaggregation (Hiemstra et al., 2006, personal communication). Soft bedrock will be susceptible to *in situ* brecciation, thrusting, shearing, and plucking, and the formation of attenuated or boudinaged till intraclasts, thereby contributing to subglacial till matrixes. Evidence of the liberation of bedrock fragments from the substrate comes from descriptions of bedrock rafts in tills (e.g., Ruszczynska-Szenajch, 1987; Sauer, 1978; Stalker and Mac, 1973, 1976). Few examples of comminution till exist (e.g., Croot and Sims, 1996), possibly as a direct consequence of either their rarity and/or the overlap in the definitions of comminution till and glaciotectonite.

Deformation Till

First introduced by Elson (1961), deformation till is defined as “a rock or sediment that has been disaggregated and

completely or largely homogenized by shearing in a subglacial deforming layer” (Benn and Evans, 1998). Deformation is a permanent change in shape and orientation of a material from an initial to a final state (Passchier and Trouw, 1996). Such changes are visible in a material as structures like folds, faults, and/or folia (Figure 13). In the absence of such structures a till cannot unequivocally be interpreted as deformed. Subglacial tills are commonly massive and lack any obvious macroscopic and/or microscopic evidence of deformation but many have still been interpreted as deformation tills, the massive appearance being regarded as evidence for high cumulative strains and total homogenization of source materials (e.g., Benn and Evans, 1996; Boulton, 1987; Boulton et al., 2001; Evans, 2000a; Hart et al., 1990). This has led to controversy in till recognition because massive melt-out tills may be impossible to differentiate from massive deformation till (cf. Alley, 1991; Boulton and Jones, 1979; Clayton et al., 1989; Ronnert and Mickelson, 1992). However, the term deformation till is more confidently applied to stratigraphic successions in which layered, heterogeneous sediment grades into a deformed homogeneous till (Benn

Figure 12 Glaciotectonite terminology and examples: (a) idealized vertical sequence/continuum of glacially deformed material (from Benn and Evans, 1996, after Banham, 1977). a – undeformed parent material (e.g., stratified sands and gravels); b – Type b glaciotectonite with nonpenetrative deformation (e.g., folded sands and gravels); c – Type a glaciotectonite with penetrative deformation (e.g., complexly folded, faulted, sheared, attenuated, and boudinaged sands and gravels); d – laminated or macroscopically massive till with sheared inclusions of sand and gravel (interpreted as a mixture of local glaciotectonite and far-traveled glacially transported sediment); (b) example of vertical continuum of glaciotectonites and subglacial till, Loch Quoich, Scotland (reproduced from Evans DJA, Rea BR, and Benn DI (1998) Subglacial deformation and bedrock plucking in areas of hard bedrock. *Glacial Geology and Geomorphology*. <http://ggg.qub.ac.uk/ggg/papers/full/1998/rp041998/rp04.html>). Folded glaciolacustrine sediments (Type b glaciotectonite) are exposed as vertically inclined beds at the base of the exposure (logs record the prefolded vertical sequence). Type a glaciotectonite at the center of the exposure lies in fault contact with the underlying Type b glaciotectonite and is capped by massive to laminated till.

and Evans, 1996). Therefore, unless evidence can be found in support of a till having been produced by homogenization during deformation, the term deformation till is best avoided.

Differentiation of melt-out and deformation tills is controversial even where sedimentary and structural features are present. The varying states of preservation of primary sedimentary structures may constitute evidence for depositional/

deformational continuums. The spatial and temporal mosaic of subglacial processes may also give rise to melt-out/deformation continuums where subglacial sediment released from the ice base by melting is then deformed in its uppermost layers, thereby preserving soft sediment intraclasts and structures to varying degrees in the resulting till sequence (Evans, 1994; Larsen et al., 2004).

Figure 13 Examples of diamictic sediments interpreted as deformation till: (a) Skipsea Till at Filey (UK), clearly showing fold structures due to preferential weathering of sand-rich intratill wisps. In the absence of such weathering the till appears macroscopically massive; (b) intensely folded multiple tills at the Cameron Ranch section in southern Alberta (USA). Each till unit displays textural banding, thereby allowing the identification of strain signature.

The basal contacts of deformation tills with underlying sediments can vary due to rheological contrasts, porewater pressure differences, and the generation of perturbations such as folds. A sharp, erosional boundary, often marked by slickensided surfaces, suggests a shear plane (Boulton et al., 2001; Ehlers and Stephan, 1979). A shear zone may also develop,

where the two materials become mixed (Hooyer and Iverson, 2000). Other structures associated with the base of deforming-layer tills include incorporated or plucked intraclasts/smudges and highly attenuated, folded and boudinaged laminae of underlying sediment (e.g., Boulton, 1987; Evans, 2000b; Hicock and Dreimanis, 1989, 1992a,b). The laminae may be vertically stacked in the till and thereby represent tectonic slices produced during sequential phases of deformation till accumulation (Boulton et al., 2001) or they may be the product of large numbers of folding and attenuation events which have stretched them out to produce 'glaciotectonic laminae' (Figure 14). This stretching may continue until the highly strained and homogenized till appears massive until viewed under the microscope (Benn and Evans, 1996; Boulton, 1987; Hiemstra and Rijdsdijk, 2003; Menzies, 2000; van der Meer, 1993).

Lee-Side Cavity-Fill Deposits

On a rigid glacier bed covered with roches moutonnées, lee-side cavities will often open up and become the depository for sediments with a wide range of characteristics related to the processes of mass flowage, fall, melt-out, and fluvial reworking (Figure 6). The resulting down-ice thinning, wedge-shaped masses of massive-to-crudely stratified diamictons with steeply dipping lenses of water-sorted sediments are classified as lee-side cavity fills ('lee-side tills' of Hillefors, 1973) and constitute a landform termed a 'crag-and-tail.' Clasts are striated and possess a strong down-valley dipping fabric (Levson and Rutter, 1986, 1989), although other characteristics of ploughing and lodgement are absent. Once a cavity closes the sediment fill is subject to reworking, including overprinting and/or truncation by the subglacial processes of ploughing, lodgement, glaciotectonic disruption, and deformation (Levson and Rutter, 1986, 1989). This may explain the apparent stratification in some glaciotectonites and deformation tills.

Subglacial Till Nomenclature

Because the processes of deformation, melt-out, flowage, sliding, lodgement, meltwater reworking, and ploughing coexist subglacially, mobilizing and transporting sediment and depositing it as various end members that range from glaciotectonically folded and faulted stratified material to texturally homogeneous diamicton (e.g., Hicock, 1990), it is important to recognize the inherent problems in genetic labeling of Quaternary tills. Moreover, the dominance of a subglacial process varies both spatially and temporally, giving rise to complex till sequences that contain a superimposed signature of former transportation/deposition at the ice-bed interface. Consequently, Evans et al. (2006) have recommended that genetic labeling of tills should be less process specific. They propose a threefold classification scheme that incorporates the process and experimentally based observations on till production and the unequivocal process-form relationships identifiable in the geological record (Figure 15). The classifications are glaciotectonite, subglacial traction till, and melt-out till.

Glaciotectonite, as defined above, can be composed of an infinite variety of parent materials, from bedrock to previously deposited Quaternary sediments. Comminution till is included

Figure 14 Examples of sedimentary structures produced by cumulative shear and the inclusion of substrate material in till due to subglacial deformation: Left: inclusion of sand lamina through the attenuation of a drag fold at the till–substrate interface. Adjacent sand wisps represent other laminae produced by earlier folding events; Right: multiple fold structures evident as attenuated, folded, and boudinaged sand laminae. Each structure is interpreted as a separate phase of deformation till accumulation, termed a tectonic/depositional slice. Reproduced from Boulton GS, Dobbie KE, and Zatzepin S (2001) Sediment deformation beneath glaciers and its coupling to the subglacial hydraulic system. *Quaternary International* 86: 3–28.

Figure 15 Conceptual model of the full spectrum of till production and depositional mechanisms resulting in a continuum of till formation. The processes depicted are those that would be expected beneath a large, predominantly temperate outlet glacier with a seasonally frozen snout. The shaded area of the glacier bed represents the subglacial traction till (STT). The final thickness of a till deposit does not reflect the thickness of the subglacial traction/deforming layer at any one point in time. Not all the process-form products would necessarily be coeval and signatures may be overprinted due to glacier advance and retreat cycles. The graphs to the right of each vertical profile log indicate the likely relative pattern of cumulative strain. The process-form products are: (a) preadvance lake sediments capped by STT; (b) lee-side cavity fill diamicts and stratified sediments capped by STT where ice has recoupled with the bed due to cavity closure. In (a) and (b), the tops of the lake sediment and cavity fill sequence are classified as glacioteconite, which is locally cannibalized and dragged into the base of the deforming till layer after folding/thrusting is induced by ice keel ploughing, clast ploughing, and/or migrations in the locus of failure planes in subglacial sediment aided by cyclical changes in porewater pressure. This produces a crudely laminated diamict; (c) sheared tills with partially to intensively glacioteconitized stratified intra- and interbeds produced over hard beds where, (i) STT and stratified interbeds (canal fills) are continually aggraded due to continuous replenishment of deformable sediment from up ice, (ii) large clasts are lodged to produce a clast pavement at the base of a thin STT in which finer grained material is continuously advected down ice, (iii) a single STT with associated glacioteconitized canal fill at a site where aggradation is restricted by poor till continuity, (iv) regelation of STT (dark gray shade) leads to the stacking of tills which later melt-out (note the similarity with sequences produced by marginal incremental thickening in (g)); (d) preadvance or remobilized melt-out till overlain by STT. The top of the melt-out till is classified as glacioteconite and is locally cannibalized and dragged into the base of the deforming till layer after folding/thrusting is induced at the STT–melt-out till interface and/or the loci of failure planes migrate through the subglacial sediment pile to produce a crudely laminated diamict; (e) glacioteconitized soft bedrock grades upwards into STT with bedrock rafts ('comminution till'); (f) glacioteconite (glacially overridden lake sediments) overlain by deforming STT where, (i) the glacioteconite has been locally cannibalized and dragged into the base of the deforming layer after folding/thrusting is induced at the STT–stratified sediment interface and/or the loci of failure planes migrate through the subglacial sediment pile to produce a crudely laminated diamict. This may be assisted by seasonal migration of the freezing front or cyclical changes in pore water pressures, (ii) the top of the glacioteconite is eroded by the base of the STT. The contact between the two sediment bodies is essentially a fault gouge; (g) glaciofluvial outwash or lake sediment, glacioteconitized in its upper layers and overlain by a stacked sequence of macroscopically massive STTs. Incremental stacking occurs where the glacier margin is stationary and slabs of STT freeze on and melt-out every year. Reproduced from Evans DJA, Rea BR, Hiemstra JF, and O Cofaigh C (2006) Genesis of glacial sediments and landforms in south-central Alberta, Canada: A critical assessment of mega-flood explanations. *Quaternary Science Reviews* 25: 1638–1667.

under this term because it is derived from the subglacial reworking of bedrock. The deformation structures displayed within glacioteconites reflect their strain history and the rheology of individual sedimentary beds. Glacioteconites can be subdivided into Type A, which display evidence of penetrative deformation, and Type B, which have undergone nonpenetrative deformation and so predeformational sedimentary structures are merely folded and faulted.

Subglacial traction till, because it is the product of a range of interrelated processes occurring in the traction zone at a glacier bed, is defined as “sediment deposited by a glacier sole either sliding over and/or deforming its bed, the sediment having been released directly from the ice by pressure melting and/or liberated from the substrate and then disaggregated and completely or largely homogenized by shearing. It includes localized lee-side cavity fills on hard beds and stratified sediments deposited by water films and channels at the ice–bed interface and within deforming subglacial sediment by Darcian and pipe flow” (Evans et al., 2006). This definition combines the inextricable subglacial process–form relationships associated with lodgement and deformation, includes the effects of substrate ploughing, and acknowledges that glacier beds are spatially and temporally changing mosaics of deformation and sliding and warm-based and cold-based conditions, implying that subglacial till end members are hybrids of the subglacial traction zone.

Melt-out till, as defined above, remains a theoretical construct and may rarely inherit and replicate the foliation and structure of its parent ice due to the severe limitations preservation potential. Melt-out tills probably occur in the geological record as both crudely stratified and macroscopically massive diamictites displaying a wide range of gravity induced disturbance structures. In situations where melt-out deposits have been overrun by glacier ice or recoupled with the glacier bed due to reactivation of ice flow, they will contain subglacial traction features and should therefore be classified as a glacioteconite.

This article is reproduced from the previous edition, volume 2, pp. 954–959, © 2007, Elsevier B.V.

Introduction

Till fabric analysis concerns the collection and processing of data on the orientation of particles in till deposits. The orientation of sand-size, or smaller, grains (matrix) is known as microfabric, and that of pebble-size or larger particles (clasts) is sometimes termed macrofabric by way of contrast. In general usage, however, 'fabric' is regarded as synonymous with macrofabric, and that sense is used here. There is a large literature on till fabric analysis, describing a wide range of analytical methods and results. Reviews of data collection techniques and analytical methods have been provided by Andrews (1971) and Benn (2004).

Data Collection

Unlithified Tills

Fabrics are usually determined in the field from a sample of clasts taken from a small region of a till deposit, using a compass-clinometer or similar instrument. The most commonly made measurements are the azimuth (compass bearing) and dip of particle long axes (L - or a -axes). However, this represents only part of the available information, and to uniquely define the orientation of any particle, it is necessary to know the azimuth and dip of one other axis or plane (Figure 1). The particle short axis (S - or c -axis) is at right angles to the a – b plane (i.e., it is the normal or pole to that plane), and provides useful information because the a – b plane, like the a -axis, is sensitive to forces experienced during deposition or deformation. For tills, the orientations of polished or fractured surfaces also provide valuable information on the origin of deposits. Taken together, measurements of a -axes, c -axes, and wear patterns can provide more insight into the origin of deposits than is possible with a -axis data alone (Benn, 1995; Hicock, 1991). However, the measurement of multiple fabric elements is time consuming and many researchers opt for the rapid collection of less comprehensive data. A sample size of 50 is usually chosen, but larger or smaller samples may be taken, depending on the aim of the investigation and the patience of the investigator. Care must be taken to avoid bias in sampling, so clasts are selected randomly from fresh vertical or horizontal exposures of the till. If the primary aim is to determine a -axis orientation, it is usual to choose only clasts for which the ratio between long and intermediate axis (a/b) is more than 1.5. This is because clasts with similar a - and b -axes will not be sensitive indicators of the forces and processes of interest.

Lithified Tills

For lithified tills, fabric measurement is complicated by the fact that the shape and orientation of clasts seen on an exposed rock

surface are not representative of the real three-dimensional (3D) fabric. The apparent long axis of a particle seen in section is not the true long axis, merely the longest dimension of the particular slice that happens to have been taken through the grain. It is possible to obtain some information on the true fabric by measuring 2D fabrics (i.e., azimuths or dips) on three polished sections oriented at right angles to each other. This approach is restricted to microfabric analysis because of the very large size of blocks required to obtain representative sample sizes for larger particles. 2D fabrics measured on bedding planes are likely to approximate true azimuth fabrics because clast long axes are commonly close to horizontal in tills, although clearly caution is recommended. If bedding planes are tilted, it is necessary to rotate the fabric data into the horizontal plane to convert them to azimuths.

Data Presentation

2D fabric data can be represented very effectively on rose diagrams. 3D data are usually plotted on stereonets or similar diagrams, in which particle axes or poles-to-planes plot as a point (Figure 2). Dips are represented by the distances of points from the center of the diagram, such that a vertically aligned particle axis plots at the exact center and a horizontally aligned axis plots on the rim. Azimuths are represented by the direction of the point relative to the center. Several variants of this type of diagram are in use, but the most common is constructed so that point densities on the diagram faithfully reflect, without distortion, data clustering in three dimensions, regardless of where on the diagram they occur. For this reason, they are known as equal-area stereonets. These diagrams may be intuitively less obvious than rose diagrams, but they communicate much more information to the trained user.

Summary Statistics

Quantitative comparison of fabric data from different sites or deposits can be done by using summary statistics. Numerous approaches have been proposed, but by far the most widely used statistics in till fabric analysis are based on the orientation tensor or eigenvalue method (Mark, 1973). This method resolves sets of azimuth and dip measurements into three orthogonal eigenvectors, V_1 , V_2 , and V_3 , where V_1 (the principal eigenvector) parallels the axis of maximum clustering in the data, and V_3 is normal to the preferred plane of the fabric. The degree of clustering of the data about the respective eigenvectors is given by the normalized vector magnitudes (eigenvalues) S_1 , S_2 , and S_3 , where $S_1 > S_2 > S_3$, and $S_1 + S_2 + S_3 = 1$. It is useful to visualize eigenvalues as three axes of ellipsoids that approximate the 'shape' of the data distribution in three dimensions.

Figure 1 Definition of particle axes (a , b , c) and planes (ab , ac , bc). Note that the c -axis is at right angles to the ab plane, and so on. The orientation and dip of at least two axes and/or planes are required to uniquely define the alignment of any particle.

Figure 2 The same a -axis fabric data plotted in two ways: a 2D rose diagram (in blue) and an equal-area stereonet (point symbols). The rose diagram gives a more immediate impression of a -axis alignment, but the stereonet contains more information. Also indicated are the direction of the principal eigenvector, V_1 and the V_1 – V_2 plane.

Figure 3(a) shows the range of all possible eigenvalue combinations, plotted on a triangular diagram analogous to those used for particle shape data. Isotropic fabrics (with data points evenly distributed in all directions) have $S_1 \approx S_2 \approx S_3$; girdles (with points evenly distributed around a great circle) have $S_1 \approx S_2 \gg S_3$; and linear clusters (with all observations approximately parallel) have $S_1 \gg S_2 \approx S_3$. **Figure 3(a)** is scaled using an isotropy index $I = S_3/S_1$, and an elongation index $E = 1 - (S_2/S_1)$, which in combination can uniquely define any ellipsoidal fabric shape. Commercially available computer programs allow rapid calculation of eigenvectors and eigenvalues, in addition to plotting data on a choice of diagram. The mathematical basis of the orientation tensor method is clearly explained by Woodcock and Naylor (1983).

Figure 3 (a) Ratios between eigenvalues used to define a three-way continuum of fabric shapes; (b) graphical representation of the Woodcock–Naylor significance test. Reproduced from Benn DI (2004) *Macrofabric*. In: Evans DJA and Benn DI (eds.) *A Practical Guide to the Study of Glacial Sediments*, pp. 93–114. London: Arnold.

Statistical Analysis

Like all samples, till fabric data represent only one of the many possible sets of measurements that could have been taken from the parent population. Thus, some of the characteristics of samples (such as apparent preferred orientations) may be statistical artifacts, rather than inherent properties of the till. Statistical significance tests can be conducted to determine the probability that sample characteristics have arisen by chance sampling effects. This is relatively straightforward for 2D data (e.g., azimuths), which can be analyzed using standard statistical methods such as chi-square (Andrews, 1971). For 3D data, the problem is considerably more complex, and rigorous analytical methods have yet to be developed. One widely adopted test determines the probability that a fabric differs from a random (i.e., isotropic) distribution (Woodcock and Naylor, 1983). This has been misapplied by some researchers

to assess the 'significance' of preferred orientations, on the mistaken assumption that it refers to the direction of the principal eigenvector V_1 . A girdle fabric (G on Figure 3(b)) is clearly 'nonrandom' because the data are clustered in a preferred plane, although they have no preferred direction. The Woodcock–Naylor test is very useful for some applications, but it should not be used to determine whether apparent preferred orientations are significant.

A new approach to the problem of significance testing was developed by Ringrose and Benn (1997) who used bootstrapping methods to construct approximate 'confidence regions' for fabric eigenvalues. Bootstrapping methods are based on the analysis of multiple resamples from an original data set, and are so-called because they appear to generate information from nowhere (analogous to lifting yourself off the ground by your bootstraps). Irrespective of their theoretical basis, bootstrapping methods perform well, and can be applied to both synthetic and field data (Benn and Ringrose, 2001; Larsen and Piotrowski, 2003). Analyses of 'confidence regions' produced in this way shows that statistical variance is largest for isotropic fabrics, and smallest for strongly clustered fabrics, implying that large ($\gg 50$) samples are required to reduce the influence of statistical effects where fabrics are 'weak' (i.e., high isotropy or low elongation), but that relatively small samples (~ 30) may suffice when fabrics are 'strong' (i.e., low isotropy and high elongation).

Sample sizes are more often decided by the energy and attention span of the researcher than statistical considerations, and methods that allow objective sampling strategies to be developed should be welcomed. Another important statistical issue is that the calculation of eigenvalues rests on the assumption that the data have a 3D Gaussian distribution, such that they vary smoothly in a prescribed way and do not exhibit more than one cluster (mode). If this is not the case, the eigenvalue method will generate spurious results and eigenvectors may lie between two or more modes in the data. While this issue is widely acknowledged, the suitability of data for eigenvalue analysis is invariably assessed on a purely visual basis. Rigorous statistical tests for 3D normality are clearly needed.

Fabric Analysis and Till Formation

Fabric analysis has been used to address two main aims. The first, which dates back to the nineteenth century (Miller, 1884), is to use preferred a -axis orientations to reconstruct former ice flow directions, and it rests on the assumption that the two are parallel. While this is undoubtedly true for certain types of subglacial deposits (e.g., lodged boulders), in some tills, fabric maxima can deviate significantly from ice flow directions indicated by other criteria. With due caution, a -axis fabric maxima can provide indicators of general ice flow directions where other forms of evidence are lacking. The second aim is to use fabric characteristics to inform reconstructions of till genesis, and it has received particular attention since the 1980s.

Numerous studies have shown that fabrics taken from different till facies tend to have distinct ranges of eigenvalues, which plot as characteristic 'envelopes' on fabric shape diagrams (Dowdeswell et al., 1985; Benn, 1994; Figure 4). Such envelopes have then been used as control data to aid the interpretation of ancient deposits of unknown origin. This

Figure 4 Eigenvalue plots of a -axis fabrics from two till facies at Breidamerkurjökull, Iceland. Solid circles: weak upper till; open circles: stiff lower till.

approach has been criticized by Bennett et al. (1999), who pointed out that there is often considerable overlap between eigenvalue envelopes for different facies, and therefore fabric eigenvalues do not constitute a unique genetic 'fingerprint.' This issue was already widely acknowledged, and does not in itself cause major problems if fabric data are interpreted in conjunction with other forms of evidence. A more fundamental problem with the use of fabric envelopes is that, for subglacial tills, the origin of even recently exposed examples is rarely well-known, and must be inferred from sedimentological characteristics (including fabric). This means that frequently there is no more information on the origin of recent tills than there is on ancient ones, so using them as analogs does not actually introduce any new information and initial misinterpretations will be perpetuated. This problem almost certainly besets the Bennett et al. data set as much as any other.

Uncertainties about the origin of control samples are compounded by the fact that many till fabrics are likely to have complex origins. Clast orientations can be affected by several processes during glacial transport and deposition, including englacial shear, drag between ice and the bed during ploughing and lodgement, and subglacial till deformation, and can be further modified by postdepositional processes such as dewatering and gravitational reworking. Most till fabrics, therefore, probably reflect complex histories, retaining memories of more than one process. Fabric overprinting is likely to be particularly important during deicing and dewatering of basal debris-rich ice, to the extent that unremoulded melt-out tills are probably very rare (Paul and Eyles, 1990). These issues clearly show that eigenvalue envelopes should not be regarded as simple templates allowing unambiguous categorization of any given deposit. Rather, they succinctly define the range of fabric shapes associated with a sediment facies, which can then be used to clarify thinking about its genesis, particularly in combination with other lines of evidence.

Significance of Till Fabrics

There has been considerable debate about the precise mechanisms that determine fabric development in subglacial environments. Two main processes have been proposed. The first,

Figure 5 Schematic diagram illustrating the concepts of (a) Jeffery, and (b) March rotation. In (a) clasts are continuously rotated as the result of vertical velocity gradients, whereas in (b) clasts passively trace the deformation of the surrounding medium.

known as Jeffery rotation, invokes the rotation of clasts in response to vertical velocity gradients in a shearing medium, which may be either ice or till (Glen et al., 1957; Hicock and Dreimanis, 1992; Figure 5(a)). Because the medium above the clast moves faster than that below, the clast is subject to a force couple, which supposedly causes clasts to continuously roll about a transverse horizontal axis. Under this process, fabrics do not settle into a final steady state, but vary continuously with a weak to moderate mean preferred orientation down-flow. Collisions between clasts are thought to produce transverse preferred orientations under sustained shearing. The second mechanism, March rotation, regards clasts as passive markers, which progressively tilt in response to strain in the surrounding medium (Figure 5(b)). During both simple and pure shear, lines are tilted towards the horizontal, rapidly at first, then by decreasing increments at high strains. Under this mechanism, clasts quickly adopt a strong preferred orientation parallel to the direction of shear, then undergo little or no change thereafter. Force couples across low-dip clasts do not result in rotation, and the overpassing medium slips over the clast instead. These contrasting mechanisms of clast orientation have been invoked to support alternative models of basal till formation.

Many massive subglacial tills have weak to moderate *a*-axis fabrics, and some researchers have argued that this reflects Jeffery rotation in viscous, subglacial deforming layers (Hart, 1994; Hicock and Dreimanis, 1992). Alternatively, Benn (1995) and Benn and Evans (1996) proposed that weak fabrics might develop by unsteady March rotation in a deforming layer, in response to fluctuations in water pressure, clast interactions, or other processes. However, Hooyer and Iverson (2000) have shown that till samples deformed to high cumulative strains in ring-shear devices invariably develop strong *a*-axis fabrics by March rotation. This result has been used to argue that tills with weak or moderate fabrics cannot represent former deforming layers (Hooyer and Iverson, 2002), but

probably form by the 'ploughing' of passive till by overpassing ice. There are, therefore, conflicting interpretations of weak fabrics in massive tills, some of which regard them as evidence for pervasive deformation, and some that argue that they are evidence against pervasive deformation.

Concluding Remarks

While ring-shear devices are extremely valuable tools that have already yielded major insights into fabric evolution and till genesis, they cannot yet control for important variables such as water pressure and sediment heterogeneity, and so are not capable of replicating the range of conditions found in nature. Consequently, it is too early to say whether till deformation always results in strong fabrics, and it is important to avoid replacing one orthodoxy (massive tills with weak fabrics = deforming beds) with another (massive tills with weak fabrics = ploughed beds). It is not known how fabrics might develop during ploughing, but it can be suggested that it will cause localized deformation, and transient, spatially variable March rotation. Thus, the ploughing process may well account for relatively weak fabrics in massive tills. Indeed, it seems probable that relatively weak fabrics can develop in subglacial tills by a variety of processes, so it is unwise to use them as evidence for one particular process without careful weighing of other evidence. The current disagreement about the meaning of till fabrics reflects a wider debate about the interpretation of till facies (Piotrowski et al., 2002, 2005; van der Meer et al., 2003). With careful research design, fabric studies have the potential to contribute significantly to this debate, particularly if multiple fabric elements are analyzed.

Erratics

The occurrence of boulders in areas far removed from their bedrock source has been recognized as incontrovertible evidence for glacial transportation since the dawn of glacial theory. Very clear and widely celebrated examples include the Scottish Ailsa Craig microgranites in the glacial sediments surrounding the Irish Sea Basin; the Scandinavian erratics in the tills of eastern England, northern Germany, Denmark, and The Netherlands; and the quartzite blocks of the 'Foothills erratics train' lying on the Cretaceous bedrock prairie of southern Alberta more than 375 km from their source in Jasper National Park (Stalker, 1956, 1976). Many such erratic trains can be easily traced to their source outcrops, for example, the Assynt sandstone boulder trains of northwest Scotland, which extend down-ice from mountains of Torridonian Sandstone (Lawson, 1995; Figure 1), but their use in the reconstruction of former transportation pathways must be tempered by an appreciation that debris transport histories may involve several glacial cycles during which ice divides and ice-flow vectors may shift dramatically. This is well illustrated by reconstructions of the complex ice flow history of the central sector of the British-Irish Ice Sheet, wherein cross-cutting subglacial bedforms and erratic transport pathways record overprinting by radically changing ice flow vectors, driven by the migration of ice dispersal centers during the last glacial cycle (Evans et al., 2009; Livingstone et al., 2008); early southerly flows from Scotland were responsible for the transport of Scottish erratics through the Tyne Gap, up the Vale of Eden and over Stainmore, toward the eastern English coast, whereas later stages of ice flow were directed northward down the Vale of Eden and into the Solway Lowlands, making Scottish erratic transport pathways puzzling to early geologists.

Indicator erratics are those for which a definite source area is known, and indicator fans are regional fields over which the erratics from particular source rocks have been dispersed by glacier flow. Indicator fans encompass the range of transport directions produced by shifting ice divides and dispersal centers, and can be identified using a range of sediment sizes, from erratic blocks down to the fine-grained matrix of tills, their recognition coming through the analysis of till matrix rather than individual erratics, in a procedure known as till provenancing or till prospecting. When combined with other glacial landforms, such as subglacial lineations and ice-scoured bedrock, the dispersal of indicator erratics can highlight large paleo-ice streams. For example, the dispersal of granite erratics from the Canadian Shield into Massey Sound and Wellington Channel in the Canadian High Arctic demarcates the operational zone of a large ice stream in the Late Quaternary Inuitian Ice Sheet (Atkinson, 2003; O'Cofaigh et al., 2000). Similarly, the 'omars' of Prest et al. (2000) are diagnostic erratics that were dispersed by the Laurentide Ice Sheet from the Belcher Islands in Hudson Bay.

Indicator Fans and Till Dispersal Indicators

The concentrations of indicator erratics vary systematically along ice-flow lines. Within indicator outcrops, concentrations increase rapidly down-glacier reflecting the addition of new material from the glacier bed, but concentrations drop off rapidly down-ice of the outcrop margin (Gillberg, 1965; Perttunen, 1977). This simple distance decay effect may be complicated by shifting patterns of erosion and sediment accumulation during glacier advance and retreat, and in some cases, the peak in erratic concentration may be displaced down-ice from the boundary of the source outcrop (Boulton, 1996). The up-ice and down-ice limits of an indicator plume are known as the head and tail, respectively (Figure 2).

Research by DiLabio and Shilts (1979) on debris dispersal by modern glaciers has demonstrated that head and tail zones are identifiable in the lateral moraines of glaciers crossing from one bedrock type to another. The transport distances of the majority of indicator erratics are relatively short. A good index of transport distance is the half-distance value, or the distance from the nearest possible source to the point at which the frequency of indicator erratics is half of its maximum. The half-distance value varies with the material resistance to abrasion and crushing and the depth to the source rock beneath superficial sediment (Bouchard and Salonen, 1990). Salonen (1986; 1987) found that the average half-distances for particles in tills in Finland are only 5 km. Very far-traveled erratics (up to 1200 km in northern Europe) may have been transported during several glacial cycles and part of their journey may have been by iceberg rafting (e.g., Marcussen, 1973).

Dyke and Morris (1988) suggested a twofold classification scheme for erratic trains based upon examples in Canada (Figure 3): (i) 'The Dubawnt type' is named after the Dubawnt sandstone in central Keewatin, which is a relatively restricted source outcrop from which material was dispersed as a plume over the surrounding bedrock by ice moving at a uniform rate over an entire region. Another example of this type of dispersal train is the 40-km long plume located down flow from the Strange Lake alkalic intrusion in northern Labrador, Canada; (ii) 'The Boothia type', based on examples on the Boothia Peninsula, is characterized by debris plumes that extend from small parts of large source areas by zones of more rapid ice flow (ice streams) within the ice sheet. Vertical changes in till composition at a particular site may result from (i) the complete erosion or burial of some source outcrops, (ii) a shift in ice-flow direction so that material is transported from different source areas, or (iii) time-dependent patterns of erratic transport along a flowline. Stea et al. (1989) and Turner and Stea (1990) have linked till characteristics to ice divide migrations in Nova Scotia during the last glaciation. Early shifts in regional ice divides led to the influx of far-traveled debris to the area, forming the Hartlen Till and Lawrencetown Till, and later local

ice dispersal resulted in the deposition of the Stony Till, with local lithological signatures.

The identification of paleo-ice lobes from till lithology has been attempted in a number of settings, and considerable success has been achieved in determining the source areas of individual till sheets in, for example, the Great Lakes region of North America (Gwyn and Dreimanis, 1979); the Canadian prairies (Shetsen, 1987); eastern England (Madgett and Catt, 1978); central Quebec and Labrador, Canada (Klassen and Thompson, 1989); and Finland (Hirvas and Nenonen, 1985), although Boston et al. (2010) have demonstrated that considerable intratill geochemical variability can arise from the stacking and cannibalization of till sheets at dynamic ice sheet margins. Dispersal patterns beneath former ice divides tend to be complex, and subglacial material can be transported in several different directions as a result of ice-divide migration. The resulting dispersal pattern consists of multiple plumes emanating from a source outcrop, termed an ‘amoeboid pattern’ by Shilts (1993). Indicator fans or dispersal fans provide important clues to the location of mineral outcrops or ore bodies in glaciated terrain, where elongate plumes of mineral-enriched tills extend down-ice from source outcrops (DiLabio, 1981; 1990; Shilts, 1976; 1993). The mineral content of the plumes is known as a mineral ‘float.’ Ore enrichment in tills can be assessed by pebble counts and/or geochemical and mineralogical analyses of the fine-grained matrix. Because ore bodies are often hidden by till, the geochemical or mineralogical characteristics of till samples, collected on a regular grid and then contoured, often reveal plume-shaped areas of metal enrichment or dispersal trains.

The largest dispersal trains can be hundreds of kilometers long but derived from very small ore bodies; they are hundreds to thousands of times larger than their source area, thus representing a much larger exploration target for prospectors than the ore body itself. Some dispersal trains can be identified visually on the basis of their color, such as the carbonate till plumes that stretch across Prince of Wales Island, Somerset Island, and Boothia Peninsula in the central Canadian Arctic archipelago (Dyke and Morris, 1988; Dyke et al., 1992) and central Baffin Island (Dredge, 2000; Dyke, 2008; Tippet, 1985).

Another excellent example is the variation in nickel concentration in till in Quebec, Canada (Shilts, 1993). The dispersal curves show only background levels of nickel up-ice from the source ultrabasic bedrock outcrop, and head and tail zones down-ice from the outcrop. The concentrations of nickel vary with grain size as a result of differential abrasion and crushing during subglacial transport. Each mineral has a different mode at which its chemical signature is strongest (‘chemical partitioning’), and this must be taken into account when analyzing till samples for their geochemical signatures (DiLabio, 1982; Nikkarinen et al., 1984; Shilts, 1991; Shilts and Wyatt, 1989).

Anomalous geochemical signals can be detected in till samples due to weathering and pedogenesis, the depth of which is dictated by such factors as the water table and grain size (e.g., Peuraniemi, 1984; Shilts, 1976; Shilts and Kettles, 1990). Therefore, till samples for geochemical analysis and indicator tracing must be taken from unweathered horizons in order to avoid postdepositional alterations such as the destruction of labile ore minerals and their depletion in till samples from above the water table.

Glacial Sequence Stratigraphy

D J A Evans, Durham University, Durham, UK

Introduction

The concept of sequence stratigraphy (see Sequence stratigraphy) has recently been adapted for application to the study of glacial depositional systems in order to understand large-scale depositional cycles in formerly glaciated basins. This approach seeks to identify large-scale sequences of conformable, genetically related strata bounded by unconformities or other major discontinuities (van Wagoner et al., 1988; Walker, 1992). Sequences comprise strata that may be grouped into systems tracts, which are defined as linkages of contemporaneous depositional systems. Traditionally, this was tailored to the study of shallow marine environments, in which systems tracts were defined in terms of major erosional and depositional episodes associated with global cycles of sea-level change, but this is not always relevant to glacial depositional settings and, therefore, modifications to the sequence stratigraphy approach have been necessary to employ it in studies of glacial sedimentology.

The characteristics of glacial sediments are dictated by the process–form relationships of specific depositional zones, such as subglacial, supraglacial, subaqueous ice-proximal, and distal and proglacial (see Glaciogenic lithofacies) environments. Glaciation is typically recorded by a stratigraphy comprising the superimposition of the deposits of these zones, documenting cycles of glacial advance and retreat. During ice sheet advance, the ice-proximal and subglacial zones migrate, in turn, over the former ice-distal zone, depositing ice-contact facies associations on top of distal sediments. Such associations tend to be eroded, transported, or redeposited in the subglacial zone once glacier ice advances over the site. As the ice sheet retreats, the ice-proximal and distal zones migrate, in turn, over the former subglacial zone, commonly blanketing subglacial forms with a fining-upward drape in subaqueous settings or glaciofluvial outwash in subaerial settings. This simple sequence can be complicated by changes between subaqueous and subaerial conditions and/or ice-marginal oscillations.

Sequence Stratigraphy Related to Glacially Influenced Sea-Level Change

A significant problem associated with applying the traditional sequence stratigraphy approach to glacial depositional settings is the fact that patterns of local sea-level change in glaciated areas are complicated by glacioisostatic depression of the crust, which results in complex sea-level histories with sea-level trends varying across glaciated basins (Andrews, 1970; Bednarski, 1988; Boulton, 1990; Dyke, 1979; Quinlan & Beaumont, 1981). A typical sequence stratigraphic signature for a glaciated marine environment subject to glacioisostatic depression is presented by Bednarski (1988) for the Canadian High Arctic, based on a modification of Curry's (1964)

definitions of transgressive and regressive sedimentary cycles (Figure 1). This depicts a depositional sequence produced during a sea-level transgression–regression cycle following on from glaciation. During deglaciation, receding ice allows marine waters to flood the basin, forming an erosional transgression surface (VII) over glaciogenic sediments or till. A sequence of marine deposits is then laid down on top of the erosion surface, interfingering with terrestrial glaciogenic sediments at the landward end (VI and V). Subsequent regression can result in erosion, which truncates glaciomarine sediments deposited during transgression and highstand (I). Alternatively, glaciomarine sediment can be reworked into littoral features such as beaches, storm ridges, or tidal flats (II, III, and IV). These 'forced regressions' associated with glacioisostatic rebound can be interrupted by short-lived transgressions due to local ice oscillations (Helle, 2004). This means that the grouping of contemporaneous depositional systems into systems tracts on the basis of regional marine erosion surfaces is impractical (Eyles & Eyles, 1992). A further significant complication arises in glacial sedimentary sequences due to the common situation where the injection of sediment into the water column from a glacier tends to be below the water level rather than at its surface (Figure 2(a)). This results in the deposition of subaqueous fans or grounding line fans (Cheel & Rust, 1982; Powell, 1990; Rust & Romanelli, 1975), which may ultimately grade to the water level to produce ice-contact deltas if glacier margins remain quasi-stable and/or sediment loads are sufficiently high (e.g., Lønne, 1995; Lønne, 2001; Lønne et al., 2001; Figure 3). This effectively renders the sequence stratigraphic terms 'highstand' and 'lowstand' meaningless in ice-contact depositional environments.

Sequence Stratigraphy Related to Terrestrial Glaciogenic Deposits

Terrestrially based glacial depositional systems, such as those accumulating in lakes or below grounded glacier ice, are generally controlled by factors other than sea-level change and so, it is necessary to modify the traditional sequence stratigraphy approach significantly. An excellent example of this is the study of Brookfield and Martini (1999), which highlights the two main controls on sequence stratigraphy in nonglacial and glacial settings as (1) the water level relative to the depositional surface, and hence the accommodation space for sediment accumulation and (2) the point of sediment injection. In nonglacial settings, these controls will vary in tandem, allowing systems tracts to be defined by the rise and fall in water level. In contrast, in glaciated basins, the accommodation space and the injection points are controlled by the water level and the position of the glacier terminus (e.g., Winsemann et al., 2004). Figure 2 shows an idealized sequence stratigraphy related to changing lake levels and glacier input points.

Figure 1 An idealized sequence stratigraphy of glaciomarine deposition on a deglaciated coastline: (a) idealized depositional sequences I–VII produced on a deglaciated coast subject to glacioisostatic depression and uplift during a glacial–deglacial cycle; (b) classification of transgressions and regressions based on the work of Curran (1964), with sedimentary sequences I–VII identified. Reproduced from Bednarski J (1988) The geomorphology of glaciomarine sediments in a high arctic fiord. *Geographie Physique et Quaternaire* 42: 65–74.

In Figure 2, a glacier snout and lake-level changes are related to the sequential change in localized depositional styles. This is translated in Figure 2(b) into spatial and temporal correlations of facies assemblages in the lake level system and the glacial input system and also shows systems tracts and bounding surfaces.

Nomenclature of Glacial Sequence Stratigraphy

Any attempt to compile a terminology that would recognize both water level and glacier input controls on glacial sequence stratigraphy would be unnecessarily complicated; hence, Brookfield and Martini (1999) have proposed the use of

allostratigraphy. This allows the construction of a descriptive and nongenetic sequence stratigraphy, wherein mappable sedimentary bodies are separated by discontinuities (Figure 2). The discontinuities or sequence boundaries can be erosional breaks caused by glacier readvance (Figure 2(b)) or the emptying of glacial lakes (e.g., Bennett et al., 2002). Glacial systems tracts can then be defined by the glacier advance-and-retreat cycle. Within the maximum glacier limits, depositional systems deposited during advance and retreat will be separated by a time-transgressive subglacial erosion surface or a wedge of subglacially deposited or deformed sediment (Berthelsen, 1978; Boulton, 1996a; Boulton, 1996b). Beyond the ice limit, complete depositional sequences may be preserved in the form of distal–proximal–distal successions, which, if they are

Figure 2 Idealized sequence stratigraphy explaining the correlation and complexity of facies assemblages due to changing lake levels and glacier input points: (a) localized control of successive units due to lake level change and ice front calving (lsf = lowstand fan; SB = sequence boundary; lsw = lowstand wedge; ts = transgressive surface; hs = highstand; smw = shelf margin wedge of shelf margin system tract; ivf = incised valley fill); (b) correlation of facies assemblages in the lake level system and the glacial input system showing systems tracts and bounding surfaces in space (A) and time (B) (WL = water level; hst = highstand systems tract; tst = transgressive systems tract; mfs = maximum flooding surface. Figure 4 Sequence stratigraphy of glaciogenic deposits of the Jurby Formation, Isle of Man, including a diamicton assemblage interpreted as a subglacial till: (a) distribution of Jurby Formation lithofacies assemblages overlying the Bishop's Court and Orrisdale Head Members of the Orrisdale Formation, (b) summary of the four lithofacies assemblage packages, (c) exploded diagram of each package showing the order of deposition, and (d) simplified reconstruction of the marginal readvances recorded by the four packages. Reproduced from [Thomas GSP, Chiverrell RC, and Huddart D \(2004\)](#) Ice-marginal depositional responses to readvance episodes in the Late Devensian deglaciation of the Isle of Man. *Quaternary Science Reviews* 23: 85–106.

directly glacier fed, will record the migration of depositional systems in response to glacier advance and retreat ([Boulton, 1990](#); [Eyles & Eyles, 1992](#)). In glaciolacustrine settings, unconformities can arise through lake drainage, which may record short-lived events or more lengthy (i.e., interstadial, interglacial) episodes. The sequence stratigraphy/allostrostratigraphy approach to deciphering complex glaciogenic deposits is well illustrated by [Thomas et al. \(2004\)](#), who recognize four off-lapping packages of lithofacies assemblages, separated from one another by unconformities or sequence boundaries, in the Jurby Formation of the Isle of Man ([Figure 4](#)). These packages record four readvances during the overall recession of the British–Irish Ice Sheet.

Introduction

Geomorphology, a subfield of geosciences, deals with landforms and related processes ([Anderson and Anderson, 2010](#)), to reveal the complex interrelations between the origin of the landform and the dynamics of its alteration caused by such processes as erosion, mass movements, or tectonics. In this regard, dating and reconstructing past geomorphic processes, the determination of recurrence intervals, and their quantification are of special interest to reveal landform development and predict future changes in light of global change. The most accurate dating technique in geosciences is dendrochronology ([Schweingruber, 1993](#)), where the outermost ring of a living tree is used for dating. Furthermore, changes in environmental conditions as well as geomorphic processes cause changes in the growth and development of trees, which are datable to the year and even the season ([Gärtner and Heinrich, 2010](#)).

The response of trees to the influence of a changing environment has been a subject of research in botany and plant physiology since the middle of the nineteenth century. Research on trees at this time focused on descriptive analysis of the structure and variability of tree rings in an ecological context and the effects of external mechanical impacts were discussed ([Schweingruber, 1996](#)). This rather holistic approach was eclipsed when Andrew Ellicott Douglass invented the revolutionary crossdating technique for tree-ring research ([Parker et al., 1984](#)). For the first time, this method enabled the accurate dating of tree rings to the year and is regarded as the backbone of tree-ring research in all fields of its application ([Schweingruber, 1996](#)). In the following decades, crossdating formed the basis for the widespread use of tree rings, mainly in archaeology and climate reconstructions ([Fritts, 1976](#)). The first attempts of reconstructing glacial fluctuations were made by [Lawrence \(1950\)](#). Since then, new ecological aspects of tree-ring research have been integrated, especially in geosciences. Fundamental research studied the effect of environmental factors such as wind on the growth of trees ([Jacobs, 1954](#)). In the early stages, this research focused on growth reactions on a

macroscopic level, although single attempts were made on a microscopic level. In the 1960s, studies on erosion rates on slopes ([LaMarche, 1968](#)) and streams ([LaMarche, 1966](#)) were also conducted using annual growth rings in roots. In the following years, tree-ring analysis was established as a standard methodology in geosciences. [Alestalo \(1971\)](#) was the first to write a monograph on the use of tree rings in dating geomorphic processes and invented the term dendrogeomorphology ([Alestalo, 1971, p. 7](#)). Since then, in parallel to the development of computers, various types of dendroecological techniques have been developed in the subfields of geosciences. Within geomorphology, these techniques facilitated the dating of land surfaces in general ([Pierson, 2007](#)), the reconstruction of hydrological conditions ([Vrobesky and Yanosky, 1990](#)), the dating of volcanic eruptions ([Salzer and Hughes, 2007](#)), and the widespread effects of earthquakes ([Jacoby, 2010](#)). Additionally, special focus was placed on reconstructing the frequencies of geomorphic processes ([Filion and Gärtner, 2010](#); [Stoffel et al., 2010](#)) such as rock fall ([Perret et al., 2006](#)), landslides ([Corominas and Moya, 2010](#)), debris flows ([Stoffel et al., 2005](#)), or creeping slopes on permafrost ([Roer et al., 2007](#)). In this context, various species-specific reaction mechanisms in stems, roots, and branches due to mechanical stresses or environmental changes have been revealed ([Gärtner and Heinrich, 2010](#)). These reactions, which have been independently used, or combined with only small modifications over the last decades, are presented in this article.

Development of Tree Rings

The development of annual rings in trees is related to secondary growth ([Schweingruber, 2007](#)). Secondary growth is initiated by the cambium, a thin layer of undifferentiated, living cells producing xylem (wood) toward the inside and phloem (bark) toward the outside of the circumference of the stem ([Figure 1](#)). In a seasonal climate, tree growth is restricted to a certain vegetation period. This period is often limited by

minimum temperatures as a threshold for initiating growth in spring and leading to an end-of-cell development in late summer or autumn. Other potential limiting growth factors are day length and precipitation. The duration of this period always depends on the environmental parameters at the specific location (Schweingruber, 1996). In a seasonal climate, the resulting tree-ring increment formed during one single vegetation period can be ascribed unmistakably to the respective calendar year.

The growth rings of coniferous and deciduous trees can be separated into earlywood and latewood, produced within the first weeks of the vegetation period and toward the end of the vegetation period, respectively. This tissue differs between conifers and deciduous trees. Rings of conifers consist of big, thin-walled tracheids in earlywood and thick-walled, tangentially flattened tracheids in latewood. Rings of deciduous trees consist of big vessels for water conductance and a stabilizing tissue of tracheids and fibers (Gärtner and Heinrich, 2010). Trees most commonly used in dendrogeomorphology are

Figure 1 Microscopic thin section of wood showing the outermost ring of a European larch tree (*Larix decidua*) including the bark. The cambium is indicated between the wood (xylem) and the bark (phloem). The cambium is a layer of tissue between xylem and phloem in most vascular plants, producing xylem cells toward the inside and phloem cells toward the outside every year. As a consequence, this layer is responsible for the diameter growth of a tree.

conifers, which are the dominant tree species in alpine areas, where the potential of natural hazards is high. Another reason is the relatively simple structure of coniferous wood, which allows a straightforward analysis (Figure 2).

The width of the single rings, as well as the proportion of earlywood and latewood, depends on environmental factors (e.g., temperature and precipitation) dominantly controlling growth. These factors vary year by year, resulting in more or less distinct ring-width variations over time. If one environmental factor is the principal limiting factor, as is most often the case with temperature or precipitation, ring-width variations in most trees of a region show a similar pattern. This similarity enables the ring-width chronologies to be crossdated on the basis of the common trends of these variations and by comparing extremely narrow or wide rings obvious in the individual tree chronologies (Figure 3).

Reference Chronologies

In general, local environments change as a result of geomorphic processes. As soon as trees are in the range of these changes, or if they are directly influenced by the process, their growth adapts to the resulting conditions. With the onset of this adaptation, ring-width variations begin to differ from the common growth variations of trees not influenced by these changes. The presence of these so-called growth anomalies, as well as their initiation, needs to be accurately dated to a calendar year. For this, all samples taken for further analysis have to be crossdated (Cook and Kairiukstis, 1990) to check for such things as false or missing rings.

Depending on the dimension and spread of the geomorphic process, more or less local chronologies have to be built, representing common site-growth variations (reference chronologies) controlled by environmental factors such as temperature, precipitation, exposure, altitude, and soil properties. The sampling for reference material should be conducted as close as possible to the area where the event to be analyzed

Figure 2 Macroscopic view (disc and core) of annual rings in conifers. The microscopic thin section on the right shows bigger, thin-walled cells of the earlywood and thick-walled, flattened cells of the latewood within an annual ring.

Figure 3 Principle of crossdating. Reproduced from Schweingruber FH (1983) *Der Jahrring: Standort, Methodik, Zeit und Klima in der Dendrochronologie*, p. 85. Berne: Paul Haupt.

happened, but definitely out of the range of its influence. This is especially important in alpine areas where environmental factors such as altitude, exposure, slope angle, precipitation, and even temperature vary over short distances.

The reference chronologies are used as a control to reveal all growth variations caused by the geomorphic process of interest. In this regard, the definition of pointer years and event years is of particular importance (Schweingruber et al., 1990). Pointer years represent extremely narrow or wide rings (compared to neighboring rings) which appear in the same calendar year in most trees of a site. They are caused by extremes of environmental factors (mostly temperature and/or precipitation), resulting in a negative (narrow ring) or positive (wide ring) effect on tree growth at the entire site. These pointer years, which should appear in the reference as well as in the disturbed chronologies, are then used to mark event years, which only occur in the chronologies disturbed by the process analyzed. Therefore, the definition of pointer years for a site or region is essential in dating geomorphic processes for two reasons: (1) they can aid during the crossdating procedure, and (2) they allow differentiation between site- and process-specific growth variations in single trees. Besides the advantages in the use of pointer years, there are also some disadvantages. It frequently happens that pointer years and process-related event years appear in the same calendar year. In these instances, the process cannot be accurately dated without further analysis of the specific structure of the respective rings (e.g., occurrence of reaction wood).

Process–Event–Response

Geomorphic processes exert various stresses on trees which alter 'normal' growth and lead to measurable growth disturbances, which can be observed macroscopically. These growth anomalies, their type, initiation, intensity, and duration permit the dating and reconstruction of such processes. Shroder (1980) coined the term 'process–event–response system' in dendrogeomorphology, that is, geomorphic processes cause specific events in the close vicinity of a tree, leading to measurable growth variations and changes in phenology as a response (Table 1). Since then, various authors have summarized possible process–event–response systems and have added new findings (Fantucci and McCord, 1995; Wiles et al., 1996). Most of these models are based on specific events with a list of the most common growth reactions likely to be found in disturbed trees.

In the following discussion, growth reactions and growth anomalies in trees are explained and related to possible processes, unlike those cited in the references mentioned earlier. This is done because a single process or event can cause various growth anomalies, depending on the way the tree is disturbed. Prior knowledge of possible growth variations as a likely response to specific geomorphic processes is of great value when decisions need to be made regarding sampling strategy, to guarantee further successful analysis. These decisions should only be reached after: (1) an accurate process

determination has been made, (2) geomorphic mapping has been done, (3) interpretation of the position of the disturbed tree relative to the related process has been made, and (4) screening is done for visible disturbances.

Growth Reactions in Trees

Growth Suppression

A more or less sudden decrease in ring width over a long period (growth suppression; **Figure 4**) is one of the most frequent features used in dendroecology to reconstruct environmental changes. Related to geomorphology, these suppressions can

Table 1 Event-related disturbances visible in tree phenology or the tree's direct environment and related growth responses

<i>Disturbance</i>	<i>Visible effect</i>	<i>Growth response</i>
Directed pressure	Tilting, bend of stem	Eccentricity (compression/tension wood)
Destabilizing ground	Tilting, bend of stem	Eccentricity (compression/tension wood), growth suppression, traumatic resin ducts
Nudation	Not visible (possibly remnants of trees in direct environment)	Growth release
Punctual impact	Scars (sometimes overgrown and for this not visible)	Callous tissue, growth suppression, traumatic resin ducts
Burial	Root collar not visible ^a	Growth suppression/growth release ^b adventitious roots
Erosion (A)	Roots partly exposed, living	Anatomical changes in annual rings of roots
Erosion (B)	Root tips exposed and mostly dead tilting of the stem, frequent	Growth suppression in stem (compare: pressure)
Water-table changes	Not visible	Growth release/suppression die-off

^aThe development of an adventitious root system may give the impression of an undisturbed root collar. In case of any doubts, the situation has to be checked by digging.

^bDepending on the material deposited around the stem.

be due to various processes leading to unfavorable conditions over a longer period, such as shearing processes affecting the root system caused by shallow landslides ([Schweingruber, 1996](#)). Mud and debris flows frequently deposit material around the lower portion of stems, which usually leads to suppressed or even missing rings, if growth is severely suppressed for 1 or more years. This is followed by a suppressed growth phase until the tree has adapted to the new situation. Avalanches also frequently lead to longer lasting growth suppressions due to such accidents as severed branches or a lifted and partly destroyed root system.

In the worst-case scenario, depending on the kind and intensity of the process, the affected trees are not able to adapt to the new conditions (e.g., deep burial of the trunk, complete shear of the root system, lowering of water table, or glacial advances) and they die. Dieback may occur abruptly after the event or start as a continuous process lasting for several years.

Succession

When destructive processes such as volcanic eruptions, avalanches, debris flows, or landslides cause a dieback or even total extinction of trees in the affected area, trees eventually recolonize these areas. This succession is always related to the recurrence intervals of the processes.

Commonly, trees start growing in the resulting open areas or on deposited material caused by singular events. Analysis of succession is also applied to glacial forefields and lateral moraines (**Figure 5**). In all cases, the age of the respective trees is of interest because process-related growth anomalies cannot be expected. To determine the age of a tree, samples have to be taken as low down the trunk as possible. In addition, the growth of the tree has to be analyzed to estimate the number of rings grown below the sample height ([Gutsell and Johnson, 2002](#)). Although age determination of these trees does not allow the precise dating of an event, it delivers a minimum age of depositional processes or the cessation of geomorphic disturbance in these areas.

Growth Release

In contrast to suppression, sudden growth releases occur as a result of environmental changes leading to more favorable

Figure 4 (a) Growth suppression. Black arrows indicate two phases: a weak suppression spanning 22 years, followed by a severe suppression lasting 64 years. (b) Growth release indicated by black arrows.

conditions for the tree (compare [Figure 4](#)). The most common event causing a growth release is the elimination of neighboring trees ([Schweingruber, 1996](#)) due to various possible processes such as debris flows, avalanches, or rock fall, leading to a reduction of competitive stresses related to an increased availability of light, water, and nutrients. Thus, depositional processes (e.g., debris flows) do not always lead to suppression, but may also stimulate a growth release. This happens, depending on type and composition of the material deposited, at the former soil surface around the base of the tree, when the depositional process causes an enrichment of nutrients and a better availability of oxygen in the soil ([Strunk, 1991](#)).

Reaction Wood

Trees that are not perturbed by any mechanical disturbances tend to grow upright, that is, vertical against the force of gravity ([Chen et al., 1999](#)). In case of a mechanical impact or instability of the ground, trees can be tilted or even displaced and, as a result, moved out of their vertical position. To compensate for the resulting imbalance, reaction wood is formed on one side of the tree for as long as a new angle of growth is maintained. This one-sided growth results in the bend of the trunk ([Figure 6](#)). Dendrogeomorphological methods are commonly applied in alpine areas to date past processes using conifers as

the preferred indicator species. This is because conifers produce compression wood (Timell, 1986) which is recognizable without elaborate analysis, if intensely pronounced, also causing changes in ring width as well as anatomical changes. In contrast, deciduous trees have rarely been used to date and reconstruct past geomorphic processes (Gers et al., 2001; Heinrich and Gärtner, 2008a). This is due to the fact that their reaction wood (tension wood) is hardly detectable macroscopically (Côté and Day, 1965). The analysis of reaction wood is mostly restricted to trees because growth reactions to tilting or destabilization of the ground are concentrated in the trunk normally growing upright. Thus, the occurrence of reaction wood can be related to external stresses. Shrubs often do not have a single trunk, so when they are mechanically stressed, the resulting reaction wood is mostly not distinguishable from the commonly occurring reaction wood. Consequently, analyzing reaction wood in shrubs cannot be done without further analysis of other wood anatomical features. In most cases, this does not lead to the desired result.

Compression Wood

By definition, compression wood is characterized by round-shaped, thick-walled tracheid cells showing intercellular spaces (Timell, 1986). Further details, such as a missing S3 layer in the cell wall and the fact that the S2 layer is characterized by helical cavities (Timell, 1973), are not visible macroscopically. Thus, this kind of analysis requires the preparation of thin sections of wood and high-resolution microscopic analyses.

Although the definition discussed earlier is commonly used, it has been repeatedly shown that compression wood

can assume various forms, depending on the species in question, physiological status of the plants (season and water content), parts of the plant affected (trunk, branches, or roots), type and duration of impact, and climatic conditions (temperature and humidity). Gärtner et al. (2001) clearly illustrated that larch (*Larix decidua* Mill.) roots form visible compression wood but lack the usual large intercellular spaces. Compression wood can be classified in up to five severity grades (Yumoto et al., 1983), each class representing a combination of distinct characters with milder forms exhibiting a lack of some compression wood characteristics such as intercellular spaces. Such a classification can be used to calibrate wood anatomical reactions to growth stresses of various forms and strengths. Furthermore, Kennedy and Farrar (1965) found in their tilting experiments that the responses of the cells varied depending on the stage of cell maturation. For example, tilting encouraged cell division during the earliest period of cell development, while at later stages the cells showed altered shapes, wall thickness, or different degrees of lignification. Thus, typical compression wood tracheids were formed only when the differentiating cells were not induced before the growth stress occurred (Figure 7).

More recent experiments focusing on the onset of compression wood resulting from stem inclination in the dormant season also showed variability in the characteristics of the first cells produced after the event. According to this, the first cells of *Larix decidua* Mill. and *Picea abies* were macroscopically characterized as common earlywood tracheids (Heinrich and Gärtner, 2008b). Wood anatomical analysis of these cells revealed that they showed certain characteristics of compression wood cells, namely, helical cavities in the S2 layer and a

Figure 7 Development of compression wood in European larch (*Larix decidua* Mill.). White arrows indicate ring boundaries ((b)–(d)). (a) Typical structure of compression wood cells in conifers. Tracheids are rounded and thick walled. Between the cells there are intercellular spaces (white triangle). (b) Compression wood cells resulting from trunk tilting after the end of the vegetation period. The first cells of the new ring are round and thick walled (compression wood). (c) Trunk tilting after the beginning of the vegetation period. First earlywood cells of the ring show the common rectangular, rather thin-walled shape. Then there is a change toward more thick-walled, rounded cells showing intercellular spaces. (d) Trunk tilting in early summer. Only the latewood cells show rounded and thick-walled compression wood cells.

Figure 8 Microscopic thin section showing tension wood formation in *Fagus sylvatica* caused by an artificial treatment (tilting of the trunk) before the beginning of the vegetation period in 2005 (black arrow indicating ring boundary 2004/2005). The ring formed in 2004 shows the highly lignified cell walls of the fiber tissue (black triangles; red color = safranin). In 2005, lignification of fiber cell walls is reduced and the cells are filled with nonlignified gelatinous fibers (white triangles; blue color = astra blue) exerting a tensile stress to the stem. + = water-conducting tissue (vessels).

missing S3 layer of the cell wall. These characteristics are not definable solely by macroscopic analysis. Experiments such as this and subsequent wood anatomical analysis can help to date such destabilizing events to a higher precision than pure macroscopic analysis.

Tension Wood

In contrast to compression wood in gymnosperms, tension wood in angiosperms is only distinguishable from normal wood by a silvery sheen macroscopically visible on trunk cross sections (Barbacci et al., 2008; Côté and Day, 1965). Thus, tension wood can be easily missed during standard tree-ring analysis, especially when working on 5 mm core samples only. Tension wood of many species is characterized by the existence of a gelatinous layer (G-layer) attached to the secondary wall of the fiber cells, sometimes filling their entire lumen (Coutand et al., 2004).

The G-layer in tension wood is usually identified in microscopic examinations in combination with specific dyes such as astra blue and safranin staining cellulose blue and lignin red, respectively (Figure 8). Many angiosperms, however, do not show a G-layer in their tension wood. Rather, they show structural modifications of the secondary wall of the fibers (Qiu et al., 2008). Furthermore, these changes of the secondary wall frequently result in the development of dense fiber tissue (increased cell-wall thickness) and are also accompanied by structural changes to the entire anatomical structure of the ring. Tilting experiments performed on European alder (*Alnus glutinosa*) and beech (*Fagus sylvatica*) resulted in a reduced number of vessels and decreased vessel size with a G-layer present in alder and absent in beech (Heinrich and Gärtner, 2008a).

The characteristics of tension wood are generally highly variable, that is, species dependent and related to the physiological

status of the plants, the parts of the plant affected, the type and duration of the mechanical impact, and climatic conditions (Wardrop, 1964). The difficulty in detecting and identifying the different forms of tension wood without microscopic examination has resulted in a lack of studies using angiosperms for the reconstruction of geomorphic processes. Nevertheless, the resulting eccentricity is measurable and can also be determined statistically (e.g., Weiss, 1991). In addition, the direction of the growth of the reaction wood can be used to reconstruct the direction of the related process (Figure 9). The occurrence of reaction wood, mostly combined with other growth anomalies, has been used in reconstructing debris flows (Gärtner et al., 2003), avalanches (Butler and Sawyer, 2008; Herbertson and Jenkins, 2003), landslides (Fantucci and McCord, 1995), and even glacier fluctuations (Fleisher et al., 2006).

Wounding (Scars)

Scars result from wounds to the cambial layer of a trunk, branch, or root of woody plants. In the circumference of the destroyed cambial zone, living, undisturbed cambium cells start producing callous tissue, which is composed of irregular cells. These cells are only produced in the vicinity of the wound and they begin to expand the growth layer into the wounded zone. In cross section, the border zone of the scar is marked by this callous tissue layer, coincident with increased growth, resulting in a subsequent overgrowing of the wound by new growth layers (Figure 10).

The cambium cells of the callous zone return to normal shape within a short time, but continue to overgrow the wound until the wound is closed, that is, when the cambial layers of both sides come in contact again, forming a continuous ring. The duration of this overgrowing process depends on the size of the scar and the productivity of the tree, varying from only a few years to centuries. The occurrence of callous tissue has been demonstrated to be an immediate reaction of trees to wounding in many species (Schweingruber, 1996). Consequently, the analysis of the onset of the first callous cells facilitates an intra-annual dating of the wound by identifying the position of the first irregular cells in the vicinity of the wound. The sample material needs to include disks, wedges from the scarred region, or core samples using the technique described by Arno and Barrett (1988) to date the initiation of scars.

The features most commonly used in dendrochronology to reconstruct environmental impacts other than geomorphic processes are fire scars. This specific type of scar occurs when the bark and the cambium below are burned, resulting in an open or sometimes hidden wound. In contrast to scars caused by mechanical impacts, fire scars show a more regular shape and contain a charred region, that is, the burned remnants of cells already developed before the fire occurred. Like other scars, fire scars can be dated to an intra-annual resolution, depending on the position where the charred region occurs within the ring (Everett, 2008).

Resin Ducts

The occurrence of resin in conifers is related to their defense system to protect the plant against mechanical wounding (Fahn et al., 1979) as well as against herbivores and pathogens

Figure 9 Disc of a coniferous tree showing eccentricity in the lower part of the cross section. Directions of compression wood are related to the direction of inclination. Using this, the direction of the process causing these reactions can be reconstructed. Arrows indicate direction of tilting; straight lines indicate optimal positions for core sampling. RA, RB, RC and RD indicate the radii needed to be analyzed to reconstruct the respective events precisely. Reproduced from Braam RR, Weiss EEJ, and Burrough PA (1987) Dendrogeomorphological analysis of mass movement. A technical note on the research methods. *Catena* 14: 585–589.

Figure 10 Stem disc indicating open and overgrown (closed) scars. Microscopic thin section: Cambium cells adjacent to the impact zone start producing irregular cells (callous tissue, white triangle), which tend to grow into the new wound followed by the succeeding process of ring growth to close the scar. Tangential rows of resin ducts are visible in the rings as a reaction to the impact process (blue color surrounding resin ducts indicates living epithelial cells producing resin; compare with [Figure 11](#)).

Figure 11 Upper part: Resin ducts and their three-dimensional distribution within a conifer trunk. The resin canals (black triangles) are surrounded by small epithelial cells (white triangle) producing the resin. This principle is true for all resin ducts (horizontal and vertical). Lower part: Microscopic thin section of a tangential row of resin ducts within the earlywood zone of an annual ring in a spruce tree.

(Nagy et al., 2005). Most conifer species produce single resin ducts within the xylem of their trunks, roots, or branches as part of this defense system, even without any stimulus from an environmental disturbance. The resin is produced in specialized cells (epithelial cells) framing the resin canals (Figure 11). The so-called resin ducts spread horizontally and vertically within the xylem, forming a three-dimensional network. In case of wounding, these ducts are concentrated in the area of the wound (Gärtner and Heinrich, 2009) forming rows of ducts directly in contact with each other, the so-called traumatic rows of resin ducts (TDs; Figure 11). Although their occurrence has sometimes been used to date geomorphic processes (Stoffel, 2008), most tree-ring related publications treat TDs as indicators for mechanical, insect-related, or other environmental disturbances, frequently describing them as a delayed response to environmental stress (Schweingruber, 2001, p. 198), not as an immediate reaction.

This supposition is mostly based on the fact that only sparse information exists on the spatial distribution of TDs within the disturbed annual ring of a mature conifer (Nagy et al., 2000). Most recent experiments have shown that TDs do not occur as an immediate reaction in Norway spruce (*P. abies*) when wounded in the dormant season. Furthermore, in European larch (*L. decidua* Mill.), they occur only as an immediate reaction in the vicinity of the wound, spreading toward the

latewood zone with increasing distance from the wound (Gärtner and Heinrich, 2009).

Various experiments conducted in recent decades have focused on the direct effect of insects or fungi and on the effect of hormones such as jasmonates, activating genes involved in the defense system of the plant (Martin et al., 2002). Since there is still no definite proof that TDs form immediately in the tissue of an annual ring after mechanical wounding in naturally grown conifers, without any immediate pathogenic or insect-related impact involved, other features such as the occurrence of callous tissue or reaction wood also need to be taken into account when dating geomorphic disturbances.

Adventitious Roots

Most tree species, especially flat-rooting conifers, are able to produce adventitious root layers when the lower part of the trunk is buried in accumulated material (Strunk, 1991). These accumulations are mostly related to flood, sheet-, mud-, or debris-flow events, and the burial of the base of the tree is easy to detect in the field, shortly after the event. Depending on the composition of the material, burial results in a reduced availability of oxygen to the root system. Therefore, buried trees initiate new roots, which, depending on the height and density of the accumulation, take over the function of the original root layer. In areas where tree bases are frequently

Figure 12 Schematic view of seven debris-flow layers influencing tree growth. Trees A, C, D, and F developed adventitious root layers after each burial event. Each layer can be dated by determining the year when the first root of a layer was initiated. Tree D died back as a result of the height of material covering the trunk. Tree F died after an erosional event exposed the uppermost adventitious root layer. Trees B and E grew up on the surface after the material was deposited. Reproduced from Strunk H (1995) *Dendrogeomorphologische Methoden zur Ermittlung der Murfrequenz und Beispiele ihrer Anwendung. Theorie und Forschung*, Band 317; *Geographie*, Band 1, p. 68. Roderer, Regensburg.

buried by geomorphic events, multiple adventitious root layers are grown (Figure 12). Spruce trees particularly tend to produce adventitious roots immediately after accumulation events happen. In other tree species, the initiation may be delayed for up to 5 years (Strunk, 1991). Consequently, at least the minimum age of depositional events can be determined. However, dating of the geomorphic event is not achieved by counting the rings of the roots at the transition to the stem, but rather by identifying the tree ring in the trunk containing the initiation of the adventitious root.

Growth Rings in Roots

The potential of analyzing radial root growth for dating purposes was already known in the first half of the last century and has been reconsidered in detail in the last decade (Krause and Morin, 1999). LaMarche (1968) determined the age of exposed roots by ring counting and then correlating the resulting age with the distance from the center of the exposed root to the recent soil surface to finally calculated erosion rates. Danzer (1996) revived the method of measuring the minimum depth of soil erosion from the degree of root exposure on datable trees. Carrara and Carroll (1979) added the idea of dating scars of exposed roots and proposed that this should be considered the first year of exposure. Despite all uncertainties, especially concerning the lack of a real cross-dating, this method is useful in areas where no data on soil erosion is available.

Anatomical Changes in Roots

It has been shown that it is possible to determine the age of adventitious roots and consequently the time of the trunk

burial caused by such things as debris-flow events. Furthermore, the age of exposed roots can be used to quantify soil erosion. Fayle (1968) studied anatomical features of exposed roots and showed the high variability of cell-structure changes due to changing environments (in this instance, contact with the atmosphere). Recent research took up this approach by focusing on the suitability of roots to date the time of exposure. Detailed analysis of structural variations in earlywood and latewood cells of coniferous trees allowed the accurate dating of the first year of exposure and also allowed differentiation between processes causing sudden or gradual exposure of coniferous roots (Gärtner et al., 2001). Specific anatomical features can be related to a sudden exposure of a root caused by an erosive event. This is an immediate 50% reduction of the size of earlywood cells and an increased number of thick-walled cells in latewood (Figure 13), resulting in a more stem-like shape of the ring. In the case of continuous denudation, cell-wall thickness and number of cells in latewood is increased first (Gärtner et al., 2001). Although the causal factors remain uncertain, these changes are not randomly distributed in the growth rings. The ability to determine the first year of exposure (Gärtner, 2007) facilitates a more detailed reconstruction of such details as sheet-erosion rates (Bodoque et al., 2005) and gully erosion (Malik, 2008).

Future Trends

The potential effects of global warming and the resulting environmental changes on the frequency and magnitude of mass movements has become an immediate problem in many mountainous regions of the world. To help address these

Figure 13 Microscopic thin sections of an unexposed (a) and an exposed (b) part of the same *Larix decidua* root due to a debris-flow event in 1978. Before 1978, both show the common cell structure of a buried root. After 1978: (a) Increasing number of earlywood tracheids but no significant change in latewood; common change in root structure near the surface. (b) Reduction of cell size in earlywood (compare cell size measurements, lower diagram), increasing thickness of cell walls in latewood, increasing number of cells. 1978: Tangential row of resin ducts.

issues, there is a need to develop new methods to record and quantify past and recent processes.

In recent years, microscopic examinations of wood samples have revealed a wide range of structural reactions of trees in response to different growth stresses. Wood anatomical investigations of the formation of compression wood, as well as tension wood, have illustrated the high variability of reaction-wood characteristics in proportion to different mechanical stresses. These results indicate the need for more

research into the calibration and verification of dendroecological methods used in geomorphology to ensure precise dating and reconstruction of different geomorphic events (Gärtner and Heinrich, 2010; Heinrich et al., 2007). There is also a need to combine millennia-long chronologies, mostly established for climate reconstructions, with dendrogeomorphic reconstructions to better understand environmental changes during the Holocene (Luckman, 2000; Solomina, 2002).

Dendroglaciology

Introduction

Dendroglaciology is a subdiscipline of dendrochronology that uses the tree-ring dating principles established by Douglass (1909, 1914) to assign ages to glacier-related sediments, landforms, and landscape processes (Koch, 2009; Luckman, 1988; Schweingruber, 1988). Common dendroglaciological methodologies include dating trees killed either directly or indirectly by glaciers, establishing the age of trees colonizing the surface of glacial deposits and landforms, and dating growth irregularities in ice-marginal forests affected by glaciers. The assigned annually resolved ages are related by various means to short- and long-term episodes of glacier expansion, retreat, and/or downwasting.

The application of tree-ring analyses to the study of glacier behavior began over 90 years ago (Cooper, 1916, 1923; Tarr and Martin, 1914). Dendroglaciological efforts have become increasingly effective as retreating glaciers expose the remains of forests overridden and buried beneath till deposits. The resulting temporal and spatial insights into Holocene glacier–climate relationships provide a framework for understanding glacier responses to future climate changes at local, regional, and global scales (Le Roy et al., 2009; Matthews and Briffa, 2005). Ring-width series contained in dendroglaciological samples have also been used to extend living tree-ring records through cross-dating (tree-ring-width pattern matching), allowing for the reconstruction of past climate conditions, and enabling the development of long-term proxy glacier mass balance records in remote areas where no instrumental data exist.

Dendroglaciological Applications

Glacially Killed Trees

Glaciers can kill trees either by expanding into standing forests, shearing their stems, and burying them beneath sediments (Allen and Smith, 2007; Luckman, 1995), or by partially burying them beneath distal proglacial outwash gravels (Garavaglia and Palfini, 2010; Wood and Smith, 2004). In recently deglaciated settings, glacially sheared stumps and boles are sometimes discovered in growth position with their roots embedded in a paleosol (Figure 1; Table 1). These remains are often found down-valley of protruding valley-side or valley-bottom bedrock outcrops, where low-pressure zones and pressed till protected them from glacial erosion and reworking (Koehler and Smith, 2011; Mathews, 1951).

Dendroglaciological remains are also commonly found within the eroded slopes and gullies of moraines where they can be deposited in various ways. In the case of composite lateral moraines composed of stacked till units deposited by successive glacier advances, the unit contacts often contain prominent wood mats comprising the remains of tree boles and stumps that colonized the moraine surface during interglacial episodes (Osborn et al., 2001; Rothlisberger et al.,

1980). While standing trees are often killed by debris spilling on distal moraine slopes, trees growing on proximal slopes are generally killed by the upward expansion of ice (Jackson et al., 2008). The latter process tends to crush and masticate trees, producing wood detritus buried at an angle reminiscent of the original moraine slope (Figure 2). Where these remains are pressed into a paleosol they can be interpreted as being near their original growth positions. In contrast, the distal spillage of rocks and boulders has a tendency to tilt and bury entire trees. Postglacial erosion of the proximal moraine face frequently distinguishes the latter as buried boles with projecting roots (Figure 3).

Intervals of glacial expansion can also be identified by dating the remains of trees that died after being submerged in glacially dammed lakes and bogs, or were buried by proglacial stream deposits. Expanding trunk valley glaciers frequently blockade unglaciated tributary valleys leading to ice-marginal ponding and flooding (Capps et al., 2011; Wiles et al., 2011) with the death date of the flooded tributary valley forests providing a convincing record of glacial expansion (Figure 4). In other situations, standing trees located downstream of glacier termini may be partially buried by outwash sediments (Garavaglia and Palfini, 2010) and their exposed apical stems sheared off by an advancing ice front (Figure 1; Wood and Smith, 2004).

Detrital tree remains and wood fragments are also commonly found in glacier forefield settings where they are encased in till, eroded from overlying moraine deposits, or scattered by glacial outwash (Allen and Smith, 2007; Osborn et al., 2007). Without stratigraphic context, however, these samples cannot be assumed to have been glacially killed as other processes (i.e., snow avalanches) may have caused their deaths (Table 1). Only where detrital remains have been pressed into an underlying paleosol and overlain by till can articulated remains be assumed to have been emplaced by an expanding glacier (Allen and Smith, 2007).

In general, bark and perimeter wood is generally absent or partially decayed on dendroglaciological samples, and minimum kill dates are assigned by cross-dating to a ‘master’ tree-ring chronology developed from living trees (Figure 5). While it is sometimes difficult to find long-lived living stands for cross-dating, multicentury and millennium-long master chronologies have been constructed using dendroglaciological samples (Barclay et al., 1999, 2009; Scuderi, 1987; Wiles et al., 2011). When cross-dating to living chronologies is not possible, samples are assigned relative ages by radiocarbon-dating (Koehler and Smith, 2011; Wood and Smith, 2004).

Surface Dating

Dendroglaciology is commonly used to assign ages to trees found growing on recently deposited surfaces (Figure 6). In these settings, tree age provides a minimum date of surface stabilization, which may in turn relate to glacier expansion

and/or retreat (Table 1; Allen and Smith, 2007; Koch, 2009; Koehler and Smith, 2011). To accurately assess the surface age, the oldest tree(s) present belonging to the first generation of colonizers must be sampled (Birks, 1980). These individuals are best located by sampling all, or as many trees as possible, at a site; particularly on well-forested surfaces where the oldest individuals may be difficult to locate (Table 2). Indicators such as species composition and the presence of coarse woody debris can help to distinguish older stands from first generation ones (Koch, 2009). In some cases, the oldest trees may be dead and these standing snags provide excellent opportunities for extending the temporal depth of calendar-dated tree-ring width chronologies (Koehler and Smith, 2011; Luckman, 1988).

On the surface of a recent deposit where only very young trees are found, stems can be cut at the tree base for ring counting (Figure 7), or an age may be assigned based on the number of annual whorls (Palmer and Miller, 1961). It is also important to consider the location of tree growth. For example,

Figure 1 Sheared stumps in growth position protruding from an ice proximal meltwater channel along the northern terminus of the Saskatchewan Glacier, Canadian Rocky Mountains, Alberta. The stumps were buried beneath the glacier until historical recession and stream incision exposed the 225- to 226-year-old stand of subalpine fir, Englemann spruce and whitebark pine trees. Cross-dating shows that all the subfossil stumps and boles exposed at this location were killed during a Neoglacial advance of the Saskatchewan Glacier in ca. 2850 ^{14}C years BP.

Figure 2 Detrital remains of tree boles and branches pressed into a paleosol and buried inside a prominent lateral moraine at Bromley Glacier, northern British Columbia Coast Mountains. The trees were killed as the glacier expanded up the proximal face of the moraine.

Figure 3 Large tree bole with attached roots eroding from the proximal face of the Franklin Glacier lateral moraine, central British Columbia Coast Mountains. The tree was killed in the early Little Ice Age as the glacier expanded down valley.

Table 1 Dendroglaciological dating methods

Type of evidence	Dating precision	Information provided	Potential limitations
Glacially killed trees	Exact calendar date of tree death	In growth position: kill date indicates glacier position at a specific time Detrital wood provides limiting date for glacial event	Requires cross-dating to determine tree age or kill date Dating precision for an event depends on preservation of wood and loss of outer rings
Surface dating	10 years or greater	Age of the oldest tree provides minimum estimate for surface age	Eccentric interval can be difficult to estimate Assumption that the oldest tree has been sampled
Abrupt change in ring symmetry as a result of tilting	Exact calendar date of tilting event	Date of eccentric or abnormal growth indicates onset of event	Event may be severe enough to kill the tree; the floating chronology would require cross-dating
Ice-contact scars	Exact calendar date of damage or ice-contact event	Damage date indicates glacier position at a specific time	Scarred, living trees are often difficult to find Dead trees require cross-dating.

Figure 4 Standing boles killed after being submerged in an ice-marginal pond during the Little Ice Age at Scimitar Glacier, central British Columbia Coast Mountains. The trees are rooted at several levels within the exposed sediments, indicating that the pond filled and drained several times as the surface of the glacier blockading the adjacent tributary valley expanded and downwasted.

trees may germinate on the distal side or crest of a moraine while ice remains in contact with the proximal side. Individuals sampled on the distal side therefore provide older and more accurate age estimates.

Samples for surface dating are best collected at the stem base where the maximum number of annual rings are present (**Figure 7**). Where destructive sampling is not possible, a tree

Figure 6 Recently deposited nested lateral moraine crests at Franklin Glacier, central British Columbia Coast Mountains. The age of the young subalpine fir trees growing on the crests provide a minimum date of surface stabilization and indicate when the glacier was no longer depositing sediment.

Figure 5 Schematic diagram illustrating how a calendar date for the growth rings of an undated wood sample (e.g., subfossil stump) can be determined by cross-dating with a dated living chronology. By anchoring the floating chronology to the living chronology, it is possible to determine the kill date of the stump and to temporally extend a chronology.

Table 2 Potential tree-ring dating errors and associated correction factors

Potential dating error	Error term	Method of calculation
OT = oldest tree	=0 if all trees are sampled	Sample all trees if possible
HE = height-age error	=0 if sampled at root crown = n , depends on height sampled above the root crown	Estimate time to grow to sampling height: – determine mean apical growth rate – sample at given intervals up the stem – factor in environmental stressors
PE = pith error	=0 if pith sampled = n , depends on years from pith	Estimate distance to pith in years based on ring curvature from similar aged trees
EI = ecesis interval	=1, . . . , n , depends on seed source, microclimate, and substrate	Calculate ecesis interval by subtracting seedling age from a known substrate age

An estimation for the minimum date of a glacial deposit (i.e., moraine) can be summarized by:
Landform date = Germination date + EI
Germination date = Age of the oldest tree = ER + HE + PE

ER = year of earliest ring.
HE = height error.
PE = pith error.

Figure 7 Schematic diagram illustrating the problems associated with coring above the root crown interface. The tree on the left is cored at a height of 1.5 m, the same height as the sapling in the middle, and the tree on the right is cored at the root crown interface. The red line in the trees and their associated cores below provides a marker year that illustrates the loss of rings (n) when determining tree age. If, for example, it took the sapling 30 years ($n = 30$) to reach the height at which the tree on the left was cored, the core taken from that tree would underestimate the age of the surface it is growing on by 30 years. The age and height of saplings growing adjacent to trees of interest is used to determine an apical growth rate (i.e., age-height correction) of 30-years/1.5 m (2 years cm^{-1}) for this example. Applied to the tree on the left, a more accurate surface date is obtained by multiplying the age-height correction by the height of the sample taken.

Figure 8 Schematic diagram illustrating the year-to-pith correction for core samples that were close to, but did not include, the pith. For an 18-year-old tree that missed the pith, a correction factor of 3 years was determined by tree-ring data (width, curvature, concentricity) of adjacent trees. For trees growing in stressed environments such as glacier forefields, the slow grow rates would likely produce missed-pith errors one order of magnitude larger.

Figure 9 Distal lateral moraine ridges at Beluga Glacier, southern British Columbia Coast Mountains. The standing snag cross-dates to a nearby tree-ring chronology. The tree died in AD 1738 shortly after deposition of the adjacent moraine. The living subalpine fir trees shown growing on the moraine ridges in the background are less than 60 years old and, accounting for an ecesis interval of 17 years (Koehler and Smith, 2011), indicate the glacier abutted this site within the last century.

core should be removed low on the stem within the root collar. These samples can be difficult to extract with the pith intact and may damage increment borers and chainsaws (Villalba and Veblen, 1997). Where early rings and/or pith cannot be extracted with repeat sampling, ring widths may be estimated using standard pith-correction methods (Table 2; Figure 8; Bosch and Gutiérrez, 1999; Villalba and Veblen, 1997). Where samples cannot be extracted at the base of a tree, various age–height corrections (Gutsell and Johnson, 2002; Wong and Lertzman, 2001), commonly based on a mean apical growth rate established from nearby trees (Table 2; McCarthy et al., 1991), may be applied to account for missing rings.

The lag time between surface stabilization and tree germination, or the ecesis interval, must also be accounted for (Table 2; Sigafos and Hendricks, 1969). Ecesis is usually assessed by establishing the number of years since a surface became ice-free or influenced by glacier processes and the point in time when trees began to germinate (Figure 9). The surface age is frequently established following examination of sequential historical images or aerial photographs (Garbarino et al., 2010; Masiokas et al., 2009; Wiles and Calkin, 1994; Winchester and Harrison, 2000). While it is recognized that ecesis is species-specific and dependent upon local geological, topographical, and microclimate controls (McCarthy and

Luckman, 1993), ecesis estimates established elsewhere or for different species are often applied to local study environments (Luckman, 1995; Smith et al., 1995; Wiles et al., 1999, 2002, 2003).

Under- or over-age estimation of a surface can occur as a result of false or locally absent tree rings. A false ring may develop if annual growth is temporarily interrupted as a result of a disturbance (Hoffer and Tardif, 2009), while radial growth may be circumferentially discontinuous or nonexistent if annual growth is suppressed (O'Neill, 1963). Although false rings can usually be recognized by their anatomical characteristics, missing rings are best identified by cross-dating comparison with established tree-ring chronologies.

Glacially Modified Trees

Dendrochronological methodologies can be used to identify instances when radial tree growth was either directly or indirectly affected by advancing glaciers. Trees record these events through various growth responses including scarring, changes in stem geometry, and changes in growth rate (Table 1; Luckman, 1988).

In some cases advancing glaciers push over and partially bury trees beneath slumped or bulldozed till deposits along their margins (Bachrach et al., 2004; Luckman, 1988). Apical stems that survive this tilting are capable of righting themselves by growing narrower upslope and/or wider downslope rings characterized by reaction wood (Figure 10). The year of inception of these rings identifies the date of the growth disturbance event (Table 1; Luckman, 1988; Villalba et al., 1990; Wiles et al., 1996). In some instances, new leader stems develop on glacially tilted trees and the age of this growth anomaly can be used to document glacial movement (Luckman, 1988). Radial growth abnormalities in trees found growing on debris-covered glaciers have also been used to monitor contemporary glaciological processes (Pelfini et al., 2007).

Glacier expansion into ice-marginal forests can result in surface abrasion and the development of callous tissue on tree stems. These scars may be dated by counting the number of rings between the year of scar formation and the subsequent growth that has occurred around the remaining circumference of the stem (Table 1; Rabassa et al., 1979). The glacial origin of these scars is particularly convincing when multiple trees exhibit scars of similar age on their ice-proximal sides (Villalba et al., 1990).

Figure 10 Schematic diagram illustrating the change in wood structure as a result of an advancing ice front tipping a tree growing in front of the glacier. The tilting of the tree results in the formation of both reaction wood and a change from concentric to distorted ring patterns on the underside of the tree. The year the tree was tilted provides a minimum date for the advance of the glacier at that location.

Changes in the growth patterns of trees that remain alive in close proximity to glaciers can reflect the timing of the arrival of ice or moraine development (Le Roy et al., 2009). The onset of cold conditions associated with encroaching ice can cause suppressed annual growth and/or the development of frost rings (Bray and Struik, 1963; Lawrence, 1950; Nicolussi and Patzelt, 1996; Villalba et al., 1990).

Climate and Glacier Mass Balance Reconstruction

Although traditional dendroglaciological techniques make it possible to date the timing of glacier advances and maximum glacier extent (Luckman, 1988), they provide little insight into the duration of glacier advances or the attendant climate conditions (Luckman, 2000; Porter, 1981). By contrast, applied dendroglaciological research has established linkages between glacier mass balance and tree-ring width variability, with Bray and Struik (1963) being among the first to relate tree-ring increments to glacial advances. LaMarche and Fritts (1971) and Matthews and Briffa (1977) later discerned that high winter snow accumulation and short, cool, and cloudy summers favored positive glacier mass balance conditions, but were detrimental to tree growth and resulted in narrow annual tree rings. Conversely, warm summer air temperatures result in

enhanced glacial ablation and the production of wider annual growth rings.

The inverse relationship between the response of climatically sensitive trees and the seasonal variables that drive glacier mass balance provides a means for developing proxy reconstructions of summer, winter, and net annual mass balance in remote areas where no such instrumental data exist (Borgaonkar et al., 2009; Brauning, 2006; Larocque and Smith, 2005; Lewis and Smith, 2004; Nicolussi and Patzelt, 1996; Watson and Luckman, 2004). In many cases these proxy records are consistent with independently constructed paleoclimate reconstructions and dated moraine sequences (Larocque and Smith, 2005; Villalba et al., 1990; Watson and Luckman, 2004; Wood et al., 2011). While inherent nonclimatic influences on radial growth (i.e., disturbance) and glacier mass balance (i.e., glacier size, geometry, debris cover) can be confounding, the temporal coherence of existing dendroglaciological proxy reconstructions highlights the influence of multiscale climate forcing mechanisms on both trees and glaciers (Watson and Luckman, 2004; Wood et al., 2011).

Despite their promise for reconstructing preinstrumental glaciological histories, tree ring derived proxy mass balance records remain limited in their applicability. Leonelli et al. (2011) indicated that tree-ring-based reconstructions of mass balance are most reliable for large, flat valley glaciers with ablation zones unobstructed by debris, also warning that they may not capture the magnitude of extreme ablation events. The paucity of historical mass balance data and high elevation records generally results in short calibration periods that limit the robustness of proxy data sets, a problem accentuated by the lagged responses of both glaciers and trees to climate shifts (Leonelli et al., 2011). The strength and direction of the relationships between both trees and glaciers to climate have also been shown to vary spatially according to elevation and other microclimate effects that are common in complex alpine environments (Leonelli and Pelfini, 2008; Splechtna et al., 2000). Recent reports of nonstationary climatic relationships between glacier behavior and ring-width growth introduce additional concerns (Leonelli et al., 2011; Wood et al., 2011).

Concluding Remarks

The use of dendroglaciological samples in the development of high-resolution, millennial-scale tree-ring records allows for the extension of both Holocene climate and glacier mass balance records. Combined with tree-ring dating these records provide a more complete temporal and spatial picture of paleoglacier–climate relationships, useful for understanding how glaciers may respond to future climates. Future research should focus on employing dendroglaciology to assess the impact of glacier size and geometry on glacier behavior over longer time intervals, closing the temporal gaps in existing dendroglaciological climate and mass balance reconstructions through targeted sampling, and addressing issues of nonstationarity and the complex relationships between tree rings, climate, and glacier mass balance in model building.

Glacial–Interglacial Scale Fluvial Responses

Introduction

Fluvial landforms and deposits are common features on the subaerial landscape, and fluvial deposits are now widely recognized on submerged continental shelves. Accordingly, fluvial landforms and deposits provide a readily studied record of terrestrial landscape evolution, and how surface processes respond to, and record, Quaternary climate change, sea-level change, and active uplift or subsidence. This article provides an overview of fluvial responses to Quaternary glacial–interglacial cycles.

History of Ideas

As recently as the 1950s and 1960s, the prevailing model for glacial–interglacial climate cycles was interwoven with, and in large part derived from, Penck and Brückner's (1909) study of terraces along tributaries to the Danube River in southern Germany. Prior to their work, Pleistocene glaciation was an accepted concept, but multiple glaciations were not yet firmly established. However, Penck and Brückner (1909) differentiated four moraines that could be traced to four separate terraces. Each terrace contained a deep weathering profile and was separated from the next younger terrace by a period of valley incision. From these data, they inferred four Pleistocene glacial–interglacial cycles, with each consisting of a long glacial, a long interglacial, and short transitions between end-member states. This 'square-wave' model for glacial–interglacial climate change (Figure 1(a)) remained dominant until the development of oxygen-isotope records from ocean basins in the 1950s–1980s.

Of equal importance, Penck and Brückner (1909) linked fluvial aggradation to glacial-period sediment supply, and incision with terrace formation to interglacial periods (Figure 1(b)). Many early studies focused on this 'glacial' versus 'interglacial' dichotomy, and assumed that present floodplains represent the Holocene, the first terrace was from the last Pleistocene glacial, the second terrace was from the previous glacial, and so on. This model was influential in the development of the climatic geomorphology popular among many twentieth century European scientists, their study established terraces and associated deposits as foci for the study of fluvial responses to climate change at the glacial–interglacial scale, and correlation of terraces to glacial periods can be found through the literature today.

Fisk's (1944) study of the Lower Mississippi Valley of the USA was similarly important. According to Fisk, the valley was deeply incised to a point some 1000 km upstream from the present shoreline due to increased channel gradients during sea-level fall and lowstand. Braided streams formed when gradients decreased during latest Pleistocene to middle Holocene

sea-level rise, with transition to a meandering regime during the late Holocene highstand (Figure 1(c)). Using this reasoning, he correlated terraces of the Lower Mississippi Valley and Gulf Coastal Plain to previous interglacial highstands. Fisk's model was 180° out of phase with Penck and Brückner (1909) in that deposition occurred during interglacials, and incision with terrace formation occurred during glacials. However, Fisk's model was equally influential in that many workers in coastal regions assigned successively older terraces to successively older interglacials.

During the 1960s–1970s, records of climate and sea-level change, and interpretations of changes in fluvial systems over time, have become increasingly independent. The development of ^{14}C dating in the 1950s provided an opportunity to develop chronological frameworks for climate change from paleobiological and other indicators, and, independently, for fluvial successions. Also in the 1950s, Leopold and Maddock's (1953) hydraulic geometry studies initiated a generation of efforts that developed quantitative relations between discharge regimes, sediment load, and measures of channel geometry. Development of ^{14}C dating and the hydraulic geometry paradigm made it possible to move beyond counting terraces and inferring correlations with glacial stages. It became clear that direct correlations between glacial–interglacial cycles and fluvial landforms were more complicated, and that fluvial systems were more sensitive to Holocene-scale climate changes than previously recognized (Knox, 1983).

The proliferation of paleobiological and geochemical data from ocean sediments in the 1960s–1980s, and acceptance of the Milankovitch theory for glacial–interglacial cycles, produced a paradigm shift in our understanding of the structure of glacial–interglacial cycles. However, in that same period, the temporal limits of ^{14}C -focused study on fluvial activity during the last 20–30 ka, the Last Glacial Maximum and the Holocene, which represents only the last 20–30% of a single 100-ka glacial–interglacial cycle. Re-examination of longer-term fluvial system evolution has been hampered by a paucity of geochronological methods that extend through a complete 100-ka glacial–interglacial cycle. Newer geochronological methods with longer time windows, for example, luminescence techniques and cosmogenic radionuclides, have been applied to fluvial landforms and deposits only in the middle to late 1990s (e.g., Blum and Price, 1998; Page et al., 1996; Phillips et al., 1997).

Glacial Versus Interglacial Worlds

Present understanding of Quaternary climate and sea-level change provides a set of global- to regional-scale boundary conditions for understanding fluvial system changes through time. For example, the new picture of glacial–interglacial cycles

Figure 1 Historical ideas. (a) Rendition of original Penck and Brückner (1909) square-wave model for Quaternary glacial-interglacial cycles. (b) Penck and Brückner (1909) model for relationships between glacial moraines and outwash terraces in the Danube drainage of southern Germany. (c) Fisk (1944) model for Mississippi River response to sea-level change. (d) Fisk model for terraces of the Gulf of Mexico coast in Louisiana.

that emerged from studies of oxygen-isotope records in deep-sea sediments provides a model for global changes in climate and ice volume, and the glacioeustatic component of sea level over the last several millions of years (Figure 2(a)). More recently, work on ice cores and the marine record shows that significant globally coherent climate changes at timescales of 10^3 – 10^4 years are superimposed on the 100-ka glacial–interglacial cycles discussed above (Figure 2(b)).

Recognition of the 100-ka frequency for middle to late Pleistocene glacial–interglacial cycles, and recognition of the variability within each cycle, clearly rendered obsolete older models for climate and sea-level change, such as Penck and Brückner (1909) or Fisk (1944). Moreover, fluvial systems

respond to climate changes within their catchments and/or relative sea-level changes at their mouths, and it is clear that global-scale forcing of climate and sea-level change are manifested regionally in a variety of ways. For example, the last glacial period was cooler than today everywhere, but changes in precipitation and discharge regimes varied in direction or magnitude from region to region. Relative sea-level changes also depart from glacioeustasy in both rate and magnitude, and sometimes in direction.

Nevertheless, one concept that can be distilled concerns the nature of average Earth system conditions, and how they depart significantly from the old square-wave model, in that full interglacials like those of the Holocene are relatively short-

Figure 2 Quaternary climate and sea-level change. (a) Oxygen-isotope record from ocean basins for the last 400 ka, illustrating 100-ka cyclicality in glacial–interglacial cycles and inferred glacioeustatic component of sea-level change. (b) Comparison of the proportion of the planktonic coldwater foraminifer *Neogloboquadrina pachyderma* (sinistral) in marine core VM 23-81 with the $\delta^{18}\text{O}$ record from the Summit Ice Core (Greenland). Dansgaard–Oeschger cycles (D–O cycles) are the millennial-scale wiggles, whereas Bond cycles are the long-term cooling trends punctuated by abrupt warming associated with Heinrich events. Reproduced from Bond G, Broecker W, Johnsen S, et al. (1993) Correlations between climate records from North Atlantic sediments and Greenland ice. *Nature* 365: 143–147.

lived, as are full glacials. Up to 80% of any middle to late Pleistocene 100-ka cycle witnessed global temperatures that were significantly cooler than a full interglacial, but not as cold as a full glacial and eustatic sea level would have been at -15 to -65 m (Porter, 1989). Hence, an average world would be one that is significantly different from today, in terms of climate, vegetation, slope stability, and sediment production. Moreover, presently submerged continental shelves were previously exposed as subaerial extensions of present-day coastal plains, and shorelines to which rivers are graded resided in mid-shelf or farther basinward positions.

Glacial Versus Interglacial Fluvial Systems

Conceptual Framework

Theory, numerical and physical modeling, and empirical studies show that valley and channel gradients, channel size and shape, and the spatial distribution of erosional and depositional landforms reflect rates of uplift or subsidence, prevailing discharge regimes, and prevailing sediment loads (Figure 3(a) and 3(b)). Channels respond to changes in these controls through a series of morphological and sedimentary adjustments, and by storing or removing sediments from valley axes (Blum and Törnqvist, 2000; Bridge, 2003; Bull, 1991; Knox, 1983). Changes in discharge regimes and sediment load can be externally forced by climate change, glaciation, and relative sea-level change; however, a number of factors make linkages between external forcing and fluvial response less than straightforward (Figure 3(c)). These include (1) spatial and temporal scale, (2) convergence of responses to different forcing mechanisms, (3) divergence of response following similar external inputs, (4) differential sensitivity, (5) lag times between time of forcing and time of response, and (6) complexity of response due to internal system dynamics (Schumm, 1991).

The record of fluvial response to glacial–interglacial cycles varies by position within a river system due to local- to regional-scale rates of uplift or subsidence, the resultant ability of fluvial systems to incise, aggrade, and modulate sediment storage over various timescales, and proximity to sea-level and the influence of relative sea-level change (Figure 3). Steep upper reaches of drainage networks within rapidly uplifting continental interiors typically have high stream powers, incising bedrock channels with discontinuous floodplains, and short residence times for sediment as a whole. Records of fluvial responses to glacial–interglacial cycles are fragmentary, and may extend only through the last glacial–interglacial period. By contrast, lower gradient mixed bedrock–alluvial valleys (sensu Howard et al., 1994) are common to the vast relatively low relief continental interiors, and tend to have more continuous floodplains and longer sediment residence times. Outside of formerly glaciated regions, mixed bedrock–alluvial valleys typically contain flights of terraces and associated fluvial deposits (Figure 4(a)) that span multiple glacial–interglacial cycles.

Alluvial valleys and alluvial-deltaic plains are common to subsiding basins, for example, passive continental margins (e.g., the US Gulf of Mexico coast, or the east coast of China) or partially flooded foreland basins (e.g., the Po Valley and

Adriatic Sea or the Tigris–Euphrates Valley and the Persian Gulf). Sediments delivered to subsiding basins are preserved in the stratigraphic record when they subside below maximum depths of incision: until that time, they can be remobilized and transported out of the basin (continental interior) or elsewhere in the basin (both continental interior and continental margin basins). For continental margin systems, remobilization is important during glacial periods when river systems extend their courses to falling stage and lowstand shorelines, and develop incised valleys (Zaitlin et al., 1994; Figure 4(b) and 4(c)). As defined here, coastal-plain incised valleys extend from the highstand shoreline to the inland limits of sea-level change, and are filled with fluvial, estuarine, and deltaic deposits, whereas cross-shelf incised valleys extend from highstand to lowstand shorelines, and may include marine facies deposited during transgression and highstand.

Continental Interior Systems

As noted above, flights of terraces have served as focal points for the study of fluvial response to glacial–interglacial cycles since the classic study of Penck and Brückner (1909). It is now recognized that long-term, time-averaged rates of valley incision within many continental interiors closely reflect rates of rock uplift, and elevational differences between terraces with adequate geochronological controls are therefore used to calculate incision rates as a proxy for long-term time-averaged uplift rates (e.g., Pazzaglia and Brandon, 2001). However, the ubiquitous presence of terrace flights also indicates that bedrock incision is a highly unsteady process when considered over glacial–interglacial timescales, such that most geologic time may actually be represented by lateral migration, cutting of bedrock straths, and deposition of overlying fluvial sediments (Figure 5).

Qualitative reasoning has therefore long suggested that many flights of terraces reflect climate-controlled unsteadiness in discharge regimes and sediment supply, superimposed on trends of uplift-controlled bedrock valley incision (Bull, 1991). In a general sense, periods of bedrock valley incision reflect times when the concentration of sediments within channels is sufficiently low such that the entire sediment thickness can be mobilized during flood events, and bedrock can be incised by the mobile sediment load. Periods of lateral migration or aggradation, in contrast, represent times when sediment concentration is sufficiently high that all sediment within the channel is not mobilized, and bedrock straths are not subject to incision. Numerical modeling by Hancock and Anderson (2002) supports these qualitative inferences, as well as the view that climate change at the glacial–interglacial scale can produce flights of terraces.

Within mixed bedrock–alluvial valleys, flights of terraces therefore likely represent the primary response to glacial–interglacial cycles. A number of studies have begun to reexamine terraces in this context, and correlate long terrace sequences to marine isotope records (e.g., Antoine, 1994; Bridgland et al., 2004; Porter et al., 1992; Figure 6). However, there remains no general model, or well-established broadly applicable relationship, that links periods of specific river behavior to specific climate conditions or transitions. Many empirical records indicate the last major period of bedrock valley

Figure 3 (a) Generalized relations between channel plan-view geometry, a dependent variable, and valley slope versus discharge. Adapted from Bridge JS (2003) *Rivers and Floodplains: Forms, Processes, and the Sedimentary Record*, p. 491. Oxford: Blackwell. (b) Balance model for aggradation and degradation of alluvial channels, emphasizing changes in the relationship between discharge and sediment supply. Channels aggrade when sediment supply exceeds transport capacity, and degrade when the reverse is true. Redrawn from a widely circulated but unpublished drawing by W. Borland of the USA Bureau of Reclamation, based on an equation by Lane (1955; Schumm SA and Ethridge FG, 1999 personal communication). Adapted from Blum MD and Straffin EC (2001) Fluvial response to external forcing: Examples from the Massif Central of France, the Texas Coastal Plain (USA), the Sahara of Tunisia, and the Lower Mississippi Valley (USA). In: Maddy D and Macklin MA (eds.) *River Basin Sediment Systems: Archives of Environmental Change*, pp. 195–228. Lisse, The Netherlands: Balkema Press. (c) Conceptual model for fluvial responses to external forcings. Forcing mechanisms, shown as independent controls on the left, are passed through a filter that defines how they are actually translated into changes in stream power (Ω) and sediment supply (q_s). Changes in these variables actually determine the direction and magnitude of fluvial stratigraphic, morphologic, and sedimentologic responses.

Figure 4 Long profile model illustrating spatial variability in river systems and the nature of their response to climate and sea-level change. In steep upper reaches, bedrock incision dominates, and terraces may be present, but the record will be fragmentary. Lower gradient mixed bedrock–alluvial valleys typically contain flights of terraces that may represent millions of years. Coastal-plain incised valleys and valley fills, as defined here, extend from the upstream limits of sea-level influence, to the highstand shoreline, whereas cross-shelf incised valleys extend from the highstand to lowstand shorelines.

incision, and terrace formation corresponds to the transition from the Last Glacial Maximum to the beginning of the Holocene interglacial: for time periods prior to the Last Glacial Maximum, there are few, if any, examples where the precise timing of lateral migration and deposition of fluvial deposits, or bedrock incision and terrace formation, is sufficiently constrained to make such linkages. Moreover, some studies interpret only one terrace from the last 100-ka glacial period, whereas other studies in the same or different areas identify multiple terraces. The record becomes less clear as one goes back in time to older glacial cycles, such that this remains a fertile topic for future research.

Regardless of the lack of precise correlations between terraces and specific climate periods, it is clear that within individual valleys, terrace surfaces commonly display differences in the morphology of formative channels. This is especially clear when comparing terrace surfaces from the last glacial period with channel patterns of modern interglacial rivers in the same valleys. Attention to morphological changes was a natural outcome of the hydraulic geometry paradigm, with early studies by Dury (1965) and Schumm (1968) discussing large-scale changes in channel geometry as a result of climate change in the US and Australia. Morphological contrasts between glacial and interglacial river systems are widely known from Europe (Figure 7(a); Starkel, 1991), where many present-day temperate regions experienced periglacial climates during glacial periods, or drained alpine glaciers or the Fennoscandian ice sheet. Many European rivers maintained braided planforms during the last glacial period, and sinuous single channels during the Holocene interglacial.

The Lower Mississippi Valley provides an example of this type of morphological response at the glacial–interglacial scale. The Mississippi was the primary conduit for sediments and meltwaters discharged from North American ice sheets, and, in some cases, routed through large ice-marginal lakes. The northern half of the 800-km-long alluvial valley contains terraces with clear braided stream patterns that stand in sharp contrast to the meanderbelts of the present day (Figure 7(b)). Braided channelbelts were interpreted by Fisk (1944) to represent the early Holocene rising stage of sea level. However, Saucier (1994) established that they were closely linked to glacial-period sediment loads and meltwater-dominated discharge regimes. Rittenour et al. (2005) provide chronological control on braided stream surfaces from luminescence dating, and show that the transition to braided stream patterns followed the isotope stage 5–4 transition, and that the reverse transformation occurred at the beginning of the Holocene with the loss of meltwaters and glacially derived sediments.

Another widespread morphological contrast between glacial and interglacial river systems can be found along the US Gulf of Mexico Coastal Plain. Many valleys in this region contain two to three distinct terraces from the last glacial period (Blum and Aslan, 2006). However, in contrast to the braided versus meandering dichotomy, terrace surfaces here display meander scars that are close to an order of magnitude larger than similar features from modern rivers in the same valleys (Figure 7(c)). Drainage basins were not glaciated, or subject to indirect effects of glaciation. Widely accepted process explanations are not yet available, but workers agree these

Figure 5 (a) Schematic model for mixed bedrock/alluvial valley setting, with flights of downward-stepping terrace surfaces and underlying fills, and a complex valley fill with multiple stratigraphic units. Older and higher terraces are commonly discontinuous and dissected, with significant thicknesses of strata removed; they also may represent long periods of time, and multiple lateral migration, aggradation, and incision events within a limited elevation range that are not readily differentiated due to degree of preservation. Younger mostly intact terraces and the complex valley fill may represent the last glacial cycle (enclosed by thick gray line). Vertical hachures represent soil profiles, with the time for surface stability and soil development represented by length of hachure. (b) Schematic continental margin setting, where sea-level fall results in development of a coastal-plain and cross-shelf incised valley system that extends through the highstand shoreline, and across the emergent shelf to the lowstand shoreline. Modified from Zaitlin BA, Dalrymple RW, and Boyd R (1994) The stratigraphic organization of incised-valley systems associated with relative sea-level change. In: Dalrymple RW, Boyd R, and Zaitlin BA (eds.) *SEPM Special Publication 51: Incised-Valley Systems: Origins and Sedimentary Sequences*, pp. 45–60. (c) Schematic model for a coastal-plain incised valley, where a cycle of sea-level fall, then rise, results in a succession of downward-stepping, then aggradational, stratigraphic units bounded by paleosols. The solid gray line encloses a single 100-ka glacial–interglacial cycle, and deposits above that line would correlate to deposits above the gray line in (a). Adapted from Blum MD and Törnqvist TE (2000) Fluvial response to climate and sea-level change: A review and look forward. *Sedimentology* 47(supplement): 1–48.

Figure 6 Idealized model for the flight of terraces in the Somme valley, northern France. Locations of key geochronological data as shown, along with suggested correlations between the terrace sequence and the marine record. In this example, each glacial–interglacial cycle in the middle to late Pleistocene has been correlated to an individual terrace, and glacial–interglacial contrasts are expressed as facies within the overall suite of deposits related to each terrace. Adapted and simplified from Bridgland D, Maddy D, and Bates M (2004). River terrace sequences: Templates for Quaternary geochronology and marine–terrestrial correlation. *Journal of Quaternary Science* 19: 203–218.

channels represent glacial-period discharge regimes and sediment loads that were significantly different than those of the present interglacial.

Sedimentological contrasts between glacial and interglacial river systems are common as well, and may ultimately provide the best indicators of changes in process through time. For example, mixed bedrock–alluvial valleys of the Loire River of central France and the Colorado River of the US Gulf of Mexico coast in Texas contain two to three terraces from the last glacial period (Blum and Straffin, 2001): the Loire was braided, whereas the Colorado River constructed the large meanders described above. Regardless of channel morphology, glacial-period deposits are dominated by coarse-grained channel-bar and channel-fill deposits, and systematically lack significant thicknesses of fine sandy and muddy overbank deposits (Figure 8(a) and 8(b)). This suggests that deep overbank flooding was not common and most floods were contained within bankfull channel perimeters during the long glacial period. By contrast, during the short Holocene, there has been little net valley incision in the Loire or Colorado systems, and minor adjustments in channel geometry. However, Holocene units contain appreciable thicknesses of overbank facies (Figure 8(c) and 8(d)), which indicates that deep overbank flooding has been important, and a significant volume of fine sediment is sequestered in overbank settings. Moreover, floodplain facies successions contain multiple weak paleosols that indicate century- to millennial-scale periods of overbank stabilization with soil development alternating with periods of deep overbank flooding and burial of paleosols. This type of high-frequency signature is lacking from the glacial period in either of these systems.

Continental Margin Systems

At some distance upstream from a highstand shoreline, fluvial systems become independent of high-frequency ($<10^6$ year)

sea-level change; mixed bedrock–alluvial valleys typical of continental interiors fall into this category. However, there can be no point moving in the downstream direction where the influence of climate-driven unsteadiness in discharge regimes and sediment load goes to zero; hence, continental margin systems must reflect the influence of both climate and sea-level change (Blum and Törnqvist, 2000).

Beginning in the 1970s and 1980s, examination of high-resolution seismic data showed that glacial period fluvial–deltaic systems had left behind an extensive record on the continental shelves (e.g., Anderson et al., 2004; Suter and Berryhill, 1985). Recent studies in a variety of settings further clarify the nature of the record in continental margin systems, and the role of different forcing mechanisms. From these studies, it is clear that the primary response to the high rates of sea-level change typical of the Quaternary is linked to regression and transgression of the shoreline to which rivers are graded: sea-level fall forces channel extension across newly emergent shelves, whereas sea-level rise forces channel shortening. Within this context, other responses are conditioned by alluvial valley, coastal plain, and shelf gradients (Figure 9), and by climate-controlled unsteadiness in discharge and sediment supply from the continental interior (Blum and Törnqvist, 2000; Ethridge et al., 1998).

At one end of a spectrum, many continental margin systems construct aggradational–progradational shorelines, or shallow subaqueous deltaic clinoforms, during sea-level highstand, through which rivers must incise when sea-level falls and channels extend across the shelves (Figure 9(a)). This type of geometry serves to partition coastal-plain and cross-shelf incised valleys, within which fluvial activity during the glacial period takes place. Valley filling during sea-level rise and highstand then produces a landward-tapering wedge of deposits that onlap fluvial deposits from the glacial period

Figure 7 Channel changes in response to glacial versus interglacial climates. (a) Channel changes in plan-view interpreted for the Prosna River in Poland (modified from Blum MD and Törnqvist TE (2000) Fluvial response to climate and sea-level change: A review and look forward. *Sedimentology* 47(supplement): 1–48; original references therein), with late Pleistocene braided channels, large early Holocene meandering channels, and small late Holocene meandering channels. (b) LANDSAT Thematic Mapper image of the northern Lower Mississippi Valley, southcentral US in Missouri, illustrating the contrast between multiple braided channelbelts from the last glacial cycle (OIS 4–2) and the modern meandering channel (map unit designations based on Rittenour et al. (2005)). Figure 9 Model for fluvial response to sea-level fall as a function of highstand coastal-plain and inner-shelf gradients. (a) Incision through coastal prism (depositional shoreline break or delta clinoform) due to steeper gradients exposed on the inner shelf as sea-level falls; (b) aggradation and progradation due to sea-level fall across a shelf that has a gradient shallower than the coastal plain. Adapted from Blum MD and Törnqvist TE (2000) *Fluvial response to climate and sea-level change: A review and look forward*. *Sedimentology* 47(supplement): 1–48; original references therein.

(Figure 10). Incised valleys of this type are known from passive and other margins with low-gradient coastal plains, where the highstand depositional shoreline break is steeper than the coastal plain or shelf (e.g., Allen and Posamentier, 1993). At the opposite end of the spectrum, steep coarse-grained rivers that discharge onto a lower-gradient shelf (Figure 9(b)) will aggrade and prograde during sea-level fall, rather than partition a distinct incised valley. During transgression, these systems backstep as well; however, studies of the Canterbury Plains, New Zealand (Leckie, 1994) show that wave erosion of the aggradational and progradational falling stage and lowstand alluvial plain results in steepening of the channel profile, and incision that propagates headward. In this type of setting, valley incision can be related to transgression and highstand.

Sea-level changes also result in the stratigraphic juxtaposition of proximal fluvial and distal fluvial–deltaic–estuarine environments and facies. Allen and Posamentier (1993) illustrate this relationship for the Gironde estuary and Garonne River of SW France (Figure 10(a)). Studies of the Rhine–Meuse in The Netherlands show that glacial-period-braided stream surfaces are overlapped by the Holocene wedge, which

Figure 10 Model for the Gironde estuary and incised valley fill, illustrating channelbelts that represent the glacial period, when sea-level fell and channels extended across the shelf, and which are onlapped by estuarine, channel, and flood plain facies associated with the transgression and highstand. Note that channelbelts deposited during falling stage and lowstand occur as terraces updip from the onlap point, and are buried farther downdip. Modified from Allen GP and Posamentier HW (1993) Sequence stratigraphy and facies model of an incised valley fill: The Gironde Estuary, France. *Journal of Sedimentary Petrology* 63: 378–391.

is dominated by anastomosing, or high-sinuosity meandering, channel patterns, and associated mud-rich alluvial–deltaic deposits (Berendsen and Stouthamer, 2001; Törnqvist et al., 2003). In this case, the glacial period shoreline was hundreds of kilometers farther basinward in the English Channel, in contrast to the upper alluvial–deltaic plain setting today. Similarly, along the US Gulf of Mexico coast in Texas, major river systems cut large coastal-plain and cross-shelf incised valleys during the last glacial period and constructed large deltas on the shelf and at the shelf margin (Figure 11; Anderson et al., 2004; Blum and Aslan, 2006; Blum and Price, 1998). In this case, terrace surfaces with the large meanders described above extend downstream into the incised valleys, where they dip below, and are onlapped by the Holocene wedge. In either case, the common theme is juxtaposition of a more coarse-grained fluvial channelbelt from the glacial period, one that formed when channels were extended to a distant shoreline, with onlapping alluvial–deltaic and estuarine facies from the transgression and highstand.

Over multiple glacial–interglacial cycles, fluvial systems can respond to repeated regressions and transgressions by constructing laterally extensive highstand alluvial–deltaic plains. Blum and Price (1998) and Blum and Aslan (2006) show that alluvial plain surfaces of the Texas coastal plain consist of multiple cross-cutting incised valley fills, with each representing a 100-ka glacial–interglacial cycle (Figure 12). Each valley fill is interpreted to represent incision and extension during glacial period falling stage and lowstand, and valley filling and alluvial plain construction during transgression and highstand (Figure 13). Each valley fill contains multiple coarse-grained channelbelts from the falling stage and lowstand, when rivers were extended to shorelines in mid-shelf or farther basinward positions, which are onlapped and buried by more mud-rich fluvial, estuarine, and deltaic facies from transgressions and highstand.

Blum and Törnqvist (2000) compiled data to illustrate the upstream limits of sea-level influence during highstands, and the distance over which channels extend during lowstands. These data suggest the landward limit of onlap due to sea-level rise correlates to sediment supply, and is inversely related to the gradient of the glacial period floodplain. Accordingly, low-gradient systems with large sediment loads will be onlapped very far upstream: for the Mississippi, this distance exceeds 300 km upstream from the highstand shoreline, whereas distances of <30–40 km apply for steep-gradient, low-sediment-supply systems. For parts of the Canterbury Plains of New Zealand, the upstream limits of sea-level influence would be defined by the upstream limits of incision during highstand, since onlap may never take place.

Distances that channels extend during lowstand reflect shelf morphology. One extreme is the Rhine, which extended into the North Sea, then was diverted southwestward through the English Channel during the last lowstand, a distance of ~800 km, and the Tigris–Euphrates, which previously extended more than 600 km through the Persian Gulf to the Arabian Sea. Large Chinese river systems extended some >400 km, whereas the Po extended ~250 km into the Adriatic Sea, and rivers of the US Gulf of Mexico coast in Texas extended 100–150 km. The Mississippi River might represent the opposite extreme: if sea level were to fall to lowstand positions now, it would not extend at all, since it now discharges to the shelf margin; however, the coarse-grained braided channels characteristic of glacial periods would likely extend downstream as far as the present-day shelf.

An important corollary to channel extension during glacial periods is the merging of drainage basins. Glacial-period rivers like the Rhine and others become the axial stream for greatly enlarged drainage basins due to the addition of systems that, in a highstand world, discharge separately to the coastal oceans

Figure 11 Map reconstructions of fluvial-deltaic systems of the US Gulf of Mexico coast and shelf in Texas. (a) Alluvial plains and deltas constructed during the last interglacial highstand, isotope stage 5. (b) Coastal-plain and cross-shelf incised valleys and deltas from the isotope stage 4–3 glacial period. (c) Coastal-plain and cross-shelf incised valleys and deltas from the isotope stage 2 full-glacial maximum lowstand. Note the merging of the Sabine, Trinity, and Brazos systems during the glacial period. (d) Holocene highstand alluvial-deltaic plains, estuaries, and barrier island systems. Figure 12 Schematic perspective view and schematic cross section of Pleistocene and Holocene alluvial plains of the Colorado River, Texas, illustrating large-scale stratigraphic architecture dominated by multiple cross-cutting paleovalley fills. Individual valley fills represent 100-ka glacial–interglacial cycles. The Holocene alluvial plain surface was recently abandoned when the channel avulsed to reoccupy an older Pleistocene meanderbelt. Modified from Blum MD and Törnqvist TE (2000) Fluvial response to climate and sea-level change: A review and look forward. *Sedimentology* 47(supplement): 1–48.

Figure 13 Schematic model for evolution of coastal-plain incised valley fills during a glacial–interglacial cycle, and development of alluvial plain successions. Reproduced from Blum MD and Price DM (1998) Quaternary alluvial plain construction in response to interacting glacioeustatic and climatic controls, Texas Gulf Coastal Plain. In: Shanley KW and McCabe PW (eds.) *SEPM Special Publication 59: Relative Role of Eustasy, Climate, and Tectonism in Continental Rocks*, pp. 31–48.

(Mulder and Syvitski, 1996). Given the nature of average climate and sea-level conditions during the Quaternary period, enlarged drainage basins such as these likely represent the norm, rather than the exception.

Conclusion

Quaternary glacial–interglacial cycles of climate and sea-level change have had a profound impact on fluvial systems. The record of this impact is spatially differentiated, such that continental interior systems reflect interactions between rates of uplift, and climate-driven unsteadiness in discharge regimes and sediment supply, whereas continental margin systems also reflect the influence of relative sea-level change. Studies of fluvial responses to glacial–interglacial cycles lag behind studies of climate and sea-level change per se, and studies in tectonic geomorphology, but nevertheless have a bright future. New geochronological methods and modeling approaches provide opportunities to more precisely define relationships between surface processes, landscapes, stratigraphic records, and glacial–interglacial cycles, quantify rates of change, and open up possibilities for developing true source-to-sink views on fluvial systems and landscape evolution.

Introduction

Throughout Earth's history, climate has oscillated from times of extreme warmth with ice-free poles (greenhouse times) to times of extreme cold with massive continental ice sheets and polar ice caps (icehouse times). Lasting for many tens of millions of years, these icehouse and greenhouse times were separated by many tens of millions of years of transitional climate. Throughout the past ~620 Ma, Earth has experienced icehouse conditions during (1) the late Vendian, the 'snowball Earth' of Hoffman et al. (1998); (2) the late Ordovician; (3) the early Carboniferous to early Permian; and (4) the late Cenozoic, since ~36.5 Ma (Figure 1). Climate oscillates at frequencies ranging from 10^0 to 10^5 years during icehouse times. As a consequence, there are times of much more extensive glaciation (glacials), lasting $\sim 10^5$ years, and of significantly less glaciation (interglacials), lasting $\sim 10^4$ years. Shorter-duration oscillations of varying climate and glacial extent (stadial and interstadials) occur on a 10^3 – 10^4 -year timescale and these help characterize glacial times. Even shorter-duration climate oscillations on the centennial, decadal, and annual timescales occur in both glacial and interglacial times. Such climatic oscillations are to be expected because the primary forces that drive climate change, which include Earth's orbital parameters, plate tectonics, solar variability, and autocyclicity within the ocean's atmosphere and cryosphere, are also in perpetual motion. Determining and quantifying the relative importance of different forcing factors in driving climate change is a challenging task and has been a major focus of debate over the last few decades.

There is broad agreement that periodic and quasiperiodic oscillations in Earth's orbital parameters of eccentricity, obliquity and precession, which affect the distribution and amount of incident solar energy, are primarily responsible for climate change on a 10^4 – 10^5 -year timescale. The relative roles of the forcing factors that result in higher frequency climate change (10^0 – 10^4 years) include changes in sunspot activity and autocyclicity within the ocean–atmosphere–cryosphere systems. This article focuses on the forcing factors that drive

climate change on timescales that are very much greater than 10^5 years.

The usual culprits of climate change on timescales much greater than 10^5 years include plate tectonic and associated changes in biogeochemical cycles. The plate-tectonic mechanisms that help drive climate change are complex. These include changes in (1) volcanism and degassing of Earth's interior; (2) rates of seafloor spreading and the formation of oceanic crust with the associated sea level changes; (3) mountain building and subduction resulting in changing rates of metamorphism and weathering, leading to changes in the concentration of atmospheric CO_2 ; (4) the latitudinal distribution and sizes of the continents; and (5) oceanic circulation resulting from opening and closing of land bridges and seaways. In turn, each of these sets of changes affects the biogeochemical cycles, which leads to changes in the composition of the oceans, the atmosphere and the biosphere that help force climate change.

Role of Tectonics on Climate Change

The debate over the role of plate-tectonic processes in driving climate change is comparatively recent. This is because plate-tectonic theories began to be formulated only in the 1960s and 1970s, and it is only during the last few decades that detailed quantitative climatic records have been developed, most significantly as a consequence of the greater availability of high-quality sediment cores recovered by the Deep Sea Drilling Program (DSDP) and Ocean Drilling Program (ODP) and improved geochemical methods. Nevertheless, hypotheses invoking uplift effects on atmospheric circulation have a long history. Notable examples include discussions in papers by Dana (1856), Lyell (1875), and Ramsay (1924), which argued that uplift of mountain regions such as the European Alps or Apennines helped drive large-scale climate change. These regions are now known to have had at the most localized cooling effects and no larger-scale impact. Later researchers such as Flint (1957), Emiliani and Geiss (1959), and Hamilton

Figure 1 The durations of the main continental ice sheets for the past 620 million years. Reproduced from Smith AG and Pickering KT (2003) Oceanic gateways as a critical factor to initiate icehouse Earth. *Journal of the Geological Society, London* 160: 337-340. The possible causes for their initiation and termination are shown.

(1968) focused mainly on smaller scale uplift in high-latitude regions to suggest a potential mechanism for the initiation of the Pleistocene continental ice sheets.

Since the 1980s, however, more attention has been given to the larger scale (global) impact of tectonics on climate change, mainly in regard to the initiation of glaciation. Of note was the work by Birchfield and Weertman (1983) who argued that the geologically youthful uplift of the Tibetan Plateau had the potential to increase snow cover and enhance global cooling. Eyles (1993) followed with his seminal work on Earth's glacial record and its tectonic setting.

BLAG Hypothesis

The first significant modern analysis of the tectonic influences on climate suggested that the driving forces for icehouse and greenhouse conditions were the result of changes in global atmospheric CO₂ concentrations associated with metamorphism and volcanic degassing along subduction zones and mid-oceanic ridges (Berner et al., 1983). Berner et al.'s (1983) proposition became known as the BLAG hypothesis (an acronym based on the initials of the authors). Together with the changing latitudinal positions of continents, the BLAG hypothesis became the leading explanation for the evolution of icehouse and greenhouse conditions until new ideas emerged in the early 1990s.

Plateau Uplift and Climate Change

Suggestions that uplift of high mountain ranges and plateaus might be more important in driving climate challenged the

BLAG hypothesis (Raymo and Ruddiman, 1992; Raymo et al., 1988). The debate emerged mainly from studies of detailed stable isotopic records, largely $\delta^{18}\text{O}$, derived from the analysis of Cenozoic deep-sea sediments. These records suggested progressive cooling, together with the realization that high plateaus, such as Tibet and the American West, had progressively uplifted during the same period. In essence, it was argued that Cenozoic uplift of plateaus changed atmospheric circulations and atmospheric concentrations of greenhouse gases (Ruddiman, 1997). The discussion centered around the effects that a rising plateau would have on the blocking of regional air systems, and changes in the position of jet streams and air masses.

In the case of the Tibetan Plateau, it was suggested that plateau uplift would have forced cold polar air into key locations in the Northern Hemisphere, particularly North America and north-west Europe, which are the sites of ice sheet development (Ruddiman, 1997, and references therein). The elevated region would have enhanced temperature-driven atmospheric flows as higher and lower atmospheric pressures developed over the plateau during the winter and summer, respectively, creating and intensifying the Asian monsoon and the aridity across the Tibetan Plateau and central Asia. The increased aridity in Central Asia would have led to a higher annual and daily temperature ranges. In addition, the elevated Tibetan Plateau would have cooled as it rose, allowing glaciers to develop, increasing albedo, and leading to further cooling. Furthermore, the greater availability of newly exposed rock surfaces and detritus produced by denudation processes would have enhanced chemical weathering, which in turn would have drawn down atmospheric CO₂. It was argued that all these processes contributed to cooling, leading to icehouse conditions and ultimately the onset of the present Ice Age.

Figure 2 Potential interactions and feedbacks between tectonic uplift and Earth's climatic and environmental system. Reproduced from Ruddiman WF and Prell WL (1997) Introduction to uplift–climate connection. In Ruddiman WF (ed.) *Tectonic Uplift and Climate Change*, pp. 1–15. New York: Plenum Press. Rectangles indicate parts of Earth's system related to tectonic (uplift); rounded rectangles indicate parts of Earth's system related to atmospheric and oceanic circulation and climate; circles indicate parts of Earth's system related to weathering and erosion; and triangles indicate the vegetational component of Earth's system.

The relationship between plateau uplift and climate change is complex and involves multiple feedback mechanisms, as is schematically illustrated in [Figure 2](#). Despite the elegant models and plausible links between plateau uplift and climate change, there is considerable uncertainty as to whether the proposed mechanisms can explain progressive cooling throughout the Cenozoic and onset of the present Ice Age. This is partially because the timing of uplift of the Tibetan Plateau, and other plateaus such as in the American West, is poorly defined. In addition, the complex feedbacks are not fully understood and the rates of weathering and drawdown of atmospheric CO_2 are not well defined. Furthermore, there were many other tectonic events occurring elsewhere on the globe during the Cenozoic that could have helped drive climate change. These included North Atlantic rift volcanism; opening and widening of two Antarctic gateways, the Tasmanian and Drake Passages ([Carter et al., 1996](#); [Latimer and Filipelli, 2002](#)); uplift of Panama and the closure of the Central American Seaway ([Roth et al., 2000](#)); and changes in the topography of the Greenland-Scotland Ridge ([Wright and Miller, 1996](#)).

Complexities of the Cenozoic Cooling and Tectonics

The stepped Cenozoic cooling trend, based on the composite marine oxygen isotope curves, the timing and extent of glaciation, major biotic events, and a simplified history of the major Cenozoic tectonic events, is shown in [Figure 3](#). The progressive decrease in $\delta^{13}\text{C}$ (a measure of the ratio of ^{13}C and ^{12}C), based

on marine carbonates, throughout the Cenozoic reflects changes in the size of the organic carbon reservoir, representing a decrease in the burial of organic matter with time. This change in burial of organic matter likely caused additional CO_2 to be released into the oceans and the atmosphere ([Raymo and Ruddiman, 1992](#)). Oxygen is necessary to oxidize organic matter and results in the release of CO_2 . The decrease in buried organic carbon, therefore, possibly reflects an increase in dissolved oxygen concentrations in the oceans, which is necessary to oxidize organic matter. Oxygen solubility increases with decreasing temperatures and hence dissolution of oxygen into the oceans would, therefore, have increased as the oceans began to cool. This in turn, would have increased the oxidation of organic matter and led to a greater release of CO_2 into the atmosphere. As the residual time of CO_2 is <1 Ma and O_2 is ~ 10 Ma in the atmosphere, this would not lead to a perfect balance between these processes. Rather the balance of the organic subcycle would become less effective with time, leading to a more intense cooling in the late Cenozoic as atmospheric CO_2 becomes progressively depleted.

Throughout the early twenty-first century, new methods devised to reconstruct the CO_2 concentration of the atmosphere on longer time scales began to test the hypothesis that a decrease in CO_2 was driving Cenozoic climate change. Of note is the work by [Pearson and Palmer \(2000\)](#) who used boron-isotope ratios in Cenozoic planktonic Foraminifera shells to estimate the pH of surface-layer seawater, which they used to reconstruct atmospheric CO_2 concentrations. In addition, [Pagani et al. \(2005\)](#) presented results on stable carbon

Figure 3 Global deep-sea oxygen and carbon isotope records based on data compiled from fine-grained carbonate-rich deep-sea sediments from more than 40 Deep Sea Drilling Program and Ocean Drilling Program sites. These are compared with the major climatic, tectonic, and biotic events. Adapted from Zachos J, Pagani M, Sloan L, Thomas E, and Billups K (2001) Trends, rhythms, and aberrations in global climate 65 Ma to present. *Science* 292: 686–693. The vertical bars provide a rough qualitative representation of volume in each hemisphere relative to the Last Glacial Maximum, with dashed bars representing periods of minimal ice ($\leq 50\%$) and full bars representing periods close to maximum ice coverage ($>50\%$ of present). The temperature scale is for bottom ocean-water temperatures based on the $\delta^{18}\text{O}$ values, but is only valid for the Cretaceous to the end of the Eocene; thereafter, the $\delta^{18}\text{O}$ values reflect a combined effect of ice volume and temperature.

isotopic values of di-unsaturated alkenones extracted from deep-sea cores to reconstruct atmospheric CO_2 concentrations from the middle Eocene to the late Oligocene ($\sim 45\text{--}25$ Ma).

The results from both methods suggested estimated atmospheric CO_2 concentrations of ~ 1000 ppm or more during much warmer climates tens of millions of years ago, compared with ice-core values of just 180–300 ppm during glacial times over the past 800 ka (Figure 4). As Ruddiman (2010) has pointed out, this long-term decrease in atmospheric CO_2 concentrations lends credence to the idea that CO_2 has been the long-term driver of global cooling; however, a closer look reveals major problems. By 22 Ma, for example, the alkenone and boron-isotope data both showed that estimated atmospheric CO_2 concentrations were already within the range typical of glacial times during the past 800 ka. Therefore, if CO_2 concentrations of 180–300 ppm have played an integral role in driving glacial cycles in the past 800 ka, one would have expected glacial cycles to have been initiated at ~ 22 Ma, rather than at ~ 2.8 Ma as suggested by the geologic evidence.

Moreover, if the average atmospheric CO_2 trend has not fallen in the past 22 Ma, then an alternative explanation is required to account for the substantial bipolar cooling during that time.

Ruddiman (2010) pointed out that the disparity between low atmospheric CO_2 and the cooling trend in the past 22 Ma could be the result of (1) something crucial having simply been overlooked; (2) one or more physical mechanisms previously proposed to account for global cooling having been much stronger than previously considered, for example, mountain uplift and/or northward movement of plates; and (3) the proxy methods to reconstruct atmospheric CO_2 concentrations having become invalid.

Ruddiman (2010) argued that the alkenone and boron-isotope proxies used between 45 and 25 Ma disagree by large amounts. For example, atmospheric CO_2 concentrations based on boron isotopes fall to very low values before those based on alkenone data. In addition, Ruddiman (2010) pointed out that there is disagreement with climate model stimulations, which suggest that atmospheric CO_2 concentrations below ~ 750 ppm

Figure 4 Indices of climate change in the past 50 Ma. Adapted from Ruddiman WF (2010) A paleoclimatic enigma? *Science* 328: 838–839. (a) Changes in circum-Arctic vegetation. (b) Changes in Antarctica ice sheet size. (c) Oxygen isotopic ($\delta^{18}\text{O}$) index of deep-ocean temperature and ice volume. (d) Estimates of past atmospheric CO_2 concentrations from alkenones (black sawtooth; data from Pagani et al., 2005) and boron-isotope ratios in Cenozoic planktonic Foraminifera shells (black circles and gray line; data from Pearson and Palmer, 2000). Paleoclimatic data from both poles indicate progressive cooling from ~50 Ma until the onset of Northern Hemisphere glaciation ~2.8 Ma, but reconstruction of atmospheric CO_2 concentrations from two prominent proxy models show very low values by 25 Ma and no subsequent decrease.

(based on boron isotopes) should cause an ice sheet to grow on Antarctica by 55–50 Ma, whereas alkenone data suggest that an ice sheet should have formed by 30 Ma, a few million years after the geologic evidence showed it to have formed. Moreover, new data presented by Tripathi et al. (2009) using B/Ca ratio predict atmospheric CO_2 concentrations of 350–450 ppm between 20 and 10 Ma (when alkenone and boron isotopes suggest 200–300 ppm). Ruddiman (2010) argued that the new studies suggest that atmospheric CO_2 did indeed decrease to drive climate and played a role in northern glacial inception, contrary to what alkenone and B-isotope proxy data suggest. Clearly, the debate is still ongoing and future studies will inevitably shed new light on this topic.

Molnar and England (1990) and England and Molnar (1990) challenged the uplift-climate hypotheses by proposing that Cenozoic cooling and increased glaciation drove mountain uplift. They argued that increased glaciation resulting in enhanced erosion results in denudational unloading and accelerated uplift of residual high mountain peaks. While this process may provide an alternative or complementary mechanism for uplift, geologic data suggest that much of the Himalayan-Tibetan orogen obtained its height before the onset of major glaciation. Nevertheless, this mechanism might be important in driving uplift in some mountain ranges.

A further twist on the role of tectonics and weathering on driving climate is provided by Willenbring and von

Figure 5 Terrigenous sediment input into the oceans through the late-Cenozoic era and atmospheric CO₂. Reproduced from Willenbring JK and von Blanckenburg F (2010) Long-term stability of global erosion rates and weathering during late-Cenozoic cooling. *Nature* 465: 211–214. Each band for CO₂ values spans the associated data points and their uncertainties. The values for terrigenous sediment accumulation in the oceans are separated into bins with an interval of 5 Ma and appear to increase abruptly during the past 5 Ma. The CO₂ data compilation is derived from a number of independent proxies and shows steady atmospheric concentrations from the mid-Miocene epoch to the present (preindustrial levels) despite the observed increase in terrigenous sediment accumulation.

Blanckenburg (2010). Until their paper, it was generally considered that there has been a fourfold increase in global sedimentation rates since ~5 Ma, a proxy for increased uplift and weathering resulting in a drawdown of atmospheric CO₂ (Figure 5). Using the ocean dissolved ¹⁰Be/⁹Be isotope system as a weathering proxy spanning the past 12 Ma, Willenbring and von Blanckenburg (2010) questioned whether this increase in global weathering and erosion actually occurred and whether the apparent increase in the sedimentation rate is due to observational biases in the sedimentary record. They argued that weathering fluxes during the late Cenozoic have been stable and that data show no clear evidence for increased erosion or any clear evidence for a pulse in weathered material into the ocean. Moreover, Willenbring and von Blanckenburg (2010) concluded that processes different from an increase in denudation caused Cenozoic global cooling, and furthermore, global cooling had no profound effect on spatially and temporally averaged weathering rates.

Matching tectonic events to global climate change is not simple. Stable marine isotope data show, for example, that Cenozoic climate change was not a gradual cooling trend, but was stepped and punctuated by periods of warming culminating in climatic optimums, which include the early Eocene Climatic Optimum, the late Oligocene Warming, and the Mid-Miocene Climatic Optimum (Figure 3). Furthermore, high-resolution δ¹⁸O data show aberrations superimposed on a long-term gradual trend that are well above the normal background variability, which last for ~10³–10⁵ years (Zachos et al., 2001). These aberrations represent changes in sea surface temperature by as much as 8 °C (Zachos et al., 2001). Carbon

isotope data suggest that the aberrations are usually accompanied by major perturbations in the global carbon cycle. The three largest ones occurred near epoch boundaries at ~55 Ma (late Paleocene Thermal Maximum aberration), 34 Ma (Oi-1 event), and 23 Ma (Mi-1 event). Changes near epoch boundaries suggest that these aberrations had a major impact on the biosphere; a point supported by accelerated rates of turnover and speciation in certain taxa groups at these times (Zachos et al., 2001). The Oi-1 and Mi-1 events are coincident with brief extremes in Antarctic ice volume and temperature, which are referred to as the Oi-1 and Mi-1 glaciations, respectively (Figure 3). The driving mechanisms for the aberrations are not known, but suggestions to explain aberrations such as the late Paleocene Thermal Maximum include the sudden release of methane from marine clathrates (compounds consisting of a lattice of water molecules with gas molecules occupying holes/cavities within the lattice; Dickens et al., 1997), abrupt deep-sea warming resulting from sudden changes in ocean circulation (Bralower et al., 1997), massive slope failure (Katz et al., 1999), and rapid release of greenhouse gases generated by heating of organic-rich sediments around intrusions in the NE Atlantic (Svensen et al., 2010). In addition, Zachos et al. (2001) suggest possible tectonic factors to explain the Oi-1 and Mi-1 events.

Drifting Continents and Oceanic Gateways

Smith and Pickering (2003) proposed a unifying explanation for the four major icehouses, which involves two sets of plate-

Figure 6 Maps showing the positions of the continents and oceans during icehouse times over the last 620 million years. Reproduced from Smith AG and Pickering KT (2003) Oceanic gateways as a critical factor to initiate icehouse Earth. *Journal of the Geological Society, London* 160: 337–340.

(a) The present-day world showing high-latitude gateways that have opened (the Drake Passage and the Tasman Straits) and the equatorial gateways that have closed (Isthmus of Panama and the seaway between Indonesia and Papua New Guinea) during the Cenozoic. The dark grey areas are the estimates of ice cover during the Last Glacial Maximum. (b) Reconstruction for the mid-Carboniferous time showing the major seaway between Laurussia and Gondwana, which closed when the supercontinents collided to form Pangaea. The dark grey areas are estimates of the ice cover for the entire Permo-Carboniferous glaciation. (c) Reconstruction for the Late Ordovician showing the estimates of ice cover (in dark grey). If Laurentia and Gondwana are brought into contact by sliding one or other supercontinent along paleolatitude lines, then NW South America joins Central America. The continents were farther apart before and after this time suggesting that an open gateway could have existed here just before and just after 444 Ma. The closure at 444 Ma might have caused effects analogous to the closing of the Isthmus of Panama changing the oceanic circulation in such a way as to initiate an ice cap, which melted once the gateway opened a million years later. (d) The Vendian map at 600 Ma. The collision of West and East Gondwana is one of the main tectonic events at this time, which eliminated a major east trending tropical seaway and may have initiated the formation of ice sheets as suggested by the Permo-Carboniferous ice age. The inverted triangles are locations of all glaciogenic deposits on Gondwana, Laurentia, Baltica, and Siberia that have been assigned to the younger Neoproterozoic.

Figure 7 Schematic diagram showing Boos and Kuang's (2010) model for the role of moisture convection rather than heat absorbed and radiated by the Tibetan Plateau. Maximum subcloud moist entropy occurs south of the Himalayas, and the heat released as water vapor rises and condenses and is reflected in peak temperatures in the overlying upper troposphere. The Himalayas keep the moist warm air over South Asia separated from the colder, drier air to the north, so the high energy of this air mass is undiluted, remains favorable for moisture-driven convection, and underlies the strength of the South Asian monsoon. Reproduced from Cane MA (2010) A moist model monsoon. *Nature* 463: 163–164.

tectonic processes. The first set involved the movement of some continents into polar latitudes, while the second set involved the opening and closing of oceanic low latitude gateways. The latter set of tectonic processes changed global oceanic circulation from one with important circum-equatorial currents (greenhouse times) to one with inhibited circum-equatorial deepwater currents (icehouse times) and more restricted oceanic gyres. Smith and Pickering (2003) stressed that all four icehouse times occurred when one or both of the geographic poles lay within or less than 1000 km from a large continent. However, there have been periods when a polar continent, such as Antarctica during much of the Cretaceous greenhouse world, was at low latitudes but was not glaciated. Thus, Smith and Pickering (2003) argued that a polar or subpolar position for a continent appears to be a necessary condition, but is not a sufficient precondition for widespread glaciation.

Smith and Pickering (2003) suggested that during icehouse times, the distribution of continents inhibited circum-equatorial circulation, forcing faster oceanic circulation in the main ocean gyres. Whether increased circulation increases snow and ice accumulation in high-latitude regions depends in part on the strength of the contemporaneous circum-polar circulation. Smith and Pickering (2003) stressed that the problem is complex, but once oceanic circulation has changed, then all the isotopic effects follow. Only after the continental configurations, gateways, and associated ocean gyres are established do CO₂ concentrations, Milankovitch-forcing, and other processes become significant in driving glacial–interglacial events. Smith and Pickering (2003) also acknowledged that high topography may be an important factor in driving climate change, but do not attempt to quantify its impact. The major tectonic factors that are likely responsible for each of the four

icehouse times are summarized in Figure 1 and illustrated in Figure 6.

General Circulation Modeling

In recent years, much effort has focused on examining the complex links between tectonics and climate change using general circulation models (GCMs) (Cliff et al., 2010). GCMs involve simulation of atmospheric circulation using high-speed computers or supercomputers to linking a system of equations used to describe atmospheric and ocean-water motion, the heat exchange and fluxes within this system, and the consequences. GCMs allow inputs such as the configurations and shapes of the oceans, continents, and mountains to be varied to compute the possible resultant changes in climate. Early GCMs convincingly illustrated the effects of plateau uplift on climate and they helped initiate much research and debate (e.g., Ruddiman and Kutzbach, 1991). Subsequent models, such as those by Sloan et al. (2001) and DeConto and Pollard (2003) were more sophisticated and were able to examine detailed changes in ice sheet growth resulting from tectonic and climatic change. Of particular note is the recent work by Boos and Kuang (2010) on the uplift of the Himalayan–Tibetan region and the development of the South Asian monsoon. Their computer simulation questioned the generally accepted idea that the prime reason for the great strength of the South Asian monsoon is the heating effect of the Tibetan Plateau. Their model showed that the barrier posed by the mountains at the southern edge of the plateau is the driving factor for the monsoon, not the heating effect of the Tibetan Plateau (Figure 7). Future development of GCMs will clearly continue to shed light on the complex links and feedbacks

between tectonics and climate, and will probably initiate many new questions.

Conclusion

To summarize, long-term global climate change ($\gg 10^5$ years) is most likely driven by tectonic processes, notably, changes in the distribution and the configurations of continents, and their effect on oceanic circulation and biogeochemical cycles. The relative importance of various factors, such as plateau uplift, volcanism, and degassing and metamorphism, and their effects on biogeochemical cycles has yet to be adequately quantified. Moreover, defining the rates, magnitude, and nature of climate change and tectonic processes is a challenging proposition, and it is thus difficult to correlate between the tectonics and climate to test causal links and feedbacks. Nevertheless, new developments in analytical methods, especially with the development of high-precision geochronology and geochemical technologies, are beginning to allow the links and feedbacks between tectonics and climate to be tested at greater temporal detail and range.

Past Climates at Astronomical Timescales

Earth's history has been studded with periods when the climate was markedly colder than at others. These cold periods, the so-called Ice Ages, have, on the geological time scale, been relatively short. The most well-known are the Pre-Cambrian Ice Ages, the late Ordovician Ice Age, the Permo-Carboniferous Ice Age, and the most recent Ice Age. This most recent Ice Age, which the Earth entered 2 to 3 million years (My) ago is called the Quaternary Period and is composed of the Pleistocene and the Holocene. It was preceded by Antarctic ice-sheet formation from 25 to 10 My before present (BP) and a long cooling trend through all the Tertiary. It has been characterized by multiple switches of the global climate between glacials (with extensive ice sheets) and interglacials (with a climate warmer or less glaciated than the rest of the time). These past climates have been reconstructed from analysis of proxy data taken from deep-sea cores, ice cores, and land records. Throughout the last million years, these data have demonstrated that successive glaciation–deglaciation cycles have occurred with a dominant quasiperiodicity of 100 thousand years (ka) over which quasicycles of about 41 and 21 ka are superimposed. The astronomical theory of paleoclimates aims to explain the recurrence of these cycles (Berger, 1978, 1988). The last one covers the period from the Eemian interglacial centered about 125 ka BP to the present-day Holocene interglacial, which peaked around 6 ka BP, and includes the Last Glacial Maximum (LGM), which occurred at 21 ka BP. This LGM was documented in great detail by the Climate Long-Range Investigation Mapping and Prediction group (CLIMAP Project Members, 1976). In the Northern Hemisphere (NH), the LGM world differed strikingly from the present, having huge land-based ice sheets that reached approximately 2–3 km in thickness. Sea level was lower by at least 115 m, which represents roughly $50 \times 10^6 \text{ km}^3$ more ice than now, and the global average surface-air temperature was 5 °C below present (Gates, 1976). Aerosol loading was higher than present and carbon dioxide (CO₂) level was about 190 parts per million by volume (ppmv; Petit et al., 1999; much less than the 280 ppmv of the Pre-Industrial Revolution and the 392 ppmv of the year AD 2011).

The Astronomical Theory of Paleoclimates, a Historical Point of View

The astronomical theory is the oldest explanation of the existence of glacial periods found in the geological record of the Quaternary Ice Age. As expounded by Milankovitch (1941), this theory is currently the most popular. In broad terms, proponents of this theory claim that the changes in three of the Earth's orbital and rotational parameters have been

sufficiently large to induce significant changes in the seasonal and latitudinal distributions of incoming solar radiation, thus forcing the pattern of glacial and interglacial cycles to recur as seen in geological records.

Climatic variations at similar time scales also occurred during non-Ice-Age period (e.g., Shackleton et al., 1999) and are also tentatively explained by the astronomical theory.

Milankovitch Era

During the first decades of the twentieth century, Spitaler (1921) rejected Croll's theory (Croll, 1875). He adopted the opposite view, first put forward by Murphy (1876), that a long, cool summer and a short, mild winter are the most favorable for including a glacial. This diminution of heat during the summer season was later recognized by Brückner, Köppen, and Wegener (Brückner et al., 1925) as the decisive factor in glaciation. However, it was Milankovitch who first completed a full astronomical theory of Pleistocene ice ages, computing the numerical values of the astronomical elements and the subsequent changes in insolation and climate.

Milutin Milankovitch was a Serbian engineer–geophysicist–astronomer who was born in Dalj in 1879 and died in Beograd in 1958. Milankovitch's first book dates from 1920, but his massive special publication of the *Royal Serbian Academy of Science* was published in German in 1941, translated into English in 1969, and reedited in 1998. Milankovitch's main contribution was exploring the solar irradiances at different latitudes and seasons in great mathematical detail and relating them, in turn, with the planetary energy balance as determined by the albedo and by the reradiation in the infrared according to Stefan's law. The basis of Milankovitch's argument is that “under those astronomical conditions in which the heat budget around the summer solstice falls below average, so will summer melt, with uncompensated glacial advance being the result.”

This theory requires that the summer in northern high latitudes must be cold to prevent the winter snow from melting in such a way as to allow a positive value in the annual budget of snow and ice. This would initiate a positive feedback cooling over the Earth through a further extension of the snow cover and a subsequent increase in the surface albedo. On the assumption of a perfectly transparent atmosphere and of the northern high latitudes being the most sensitive to insolation changes, this hypothesis requires a minimum in the NH summer insolation at high latitudes (the so-called solar energy at the top of the atmosphere). The essential product of the Milankovitch theory is, therefore, his curve that shows how the intensity of summer sunlight varied over the past 600 ka at 65° N. Actually, he introduced the concept of the caloric season. These seasons are

exactly half-a-year long, which avoids the necessity of taking into account the variations in their length. This is not the case for the astronomical seasons whose lengths vary in time. The summer half-year comprises all the days during which a given mid- to high-latitude region receives more irradiation than any of the days of the winter half-year. On his curves, Milankovitch correlated certain low points in NH insolation with four European ice ages reconstructed 15 years earlier by Albrecht Penck and Eduard Brückner (Penck and Bruckner, 1909).

The Milankovitch Debate

However, when considering the Milankovitch insolation curve, we are left in no doubt that the success of the Milankovitch theory is only apparent, because the Quaternary has had many more glacial periods than was claimed during the first part of the twentieth century. In fact, until roughly 1970, the Milankovitch theory was largely disputed because the discussions were based on fragmentary geological sedimentary records and on inaccurate time scales. In addition, the climate was considered too resilient to react to 'such small changes' as those seen in the Milankovitch summer half-year caloric insolation.

Milankovitch Renaissance

In the late 1960s, judicious use of radioactive dating and other techniques gradually clarified the details of the time scale, better instrumental methods became available for the analysis of oxygen isotopes as proxies for ice-age temperatures, paleoecological analysis of sediment cores was greatly improved, global climates were reconstructed (CLIMAP Project Members, 1976), and atmospheric general circulation models (Gates, 1976) and climate models became available. Following these improvements, Hays et al. (1976) showed that quasiperiods of 100, 41, 23, and 19 ka are clearly marked in proxy records of past climate.

Independently, these periods were also found in the long-term variations of eccentricity, obliquity, and climatic precession using a new model of astronomical forcing (Berger, 1978). These results found simultaneously in geological and astronomical data constituted the most delicate proof that astronomical elements have a sizable effect on the slow evolution of climate.

These results sparked a revival of the popularity of the astronomical theory of paleoclimates. New studies were initiated in all four of the main elements of astronomical theory, namely, (i) the computation of the astronomical elements, (ii) the computation of the appropriate insolation parameters, (iii) the development of suitable climate models, and (iv) the analysis of geological data in the time and frequency domains in order to investigate the physical mechanisms that are responsible for the long-term climatic variations and to calibrate and validate the climate models.

Long-Term Variations of the Astronomical Parameters

As we are primarily interested in glacial–interglacial cycles, the focus here is only on the long-term variations of the

energy (insolation) received by the Earth from the Sun at the top of the atmosphere and at time scales of tens to hundreds of thousands of years.

The incoming solar radiation changes from day to day due to the Earth's elliptic motion around the Sun. But the seasonal and latitudinal distributions of daily insolation also have long-term variations that are related to the orbit of the Earth around the Sun and to the inclination of its axis of rotation. These involve three well-identified astronomical parameters (Figure 1): the eccentricity, e (a measure of the shape of the Earth's orbit around the Sun); the obliquity, ε (the tilt of the equator with respect to the plane of the Earth's orbit); and climatic precession, $e \sin \tilde{\omega}$, a measure of the Earth–Sun distance at the summer solstice ($\tilde{\omega}$, the longitude of the perihelion, a measure of the angular distance between the perihelion and the vernal equinox that are both in motion). The present-day value of e is 0.016. As a consequence, although the Earth's orbit is very close to a circle, the Earth–Sun distance and, consequently, the insolation vary by as much as 3.2% and 6.4%, respectively, over the course of one year. The obliquity, which defines the tropical latitudes and polar circles, is presently $23^\circ 27'$. The longitude of the perihelion is 102° , which means that the NH winter occurs when the Earth is closest to the Sun.

The secular variations of these elements of the Earth's orbit and rotation are due to the gravitational perturbations which the Sun, the other planets, and the moon exert on the Earth's orbit and axis of rotation. The solution of the system of equations that governs these motions allows the numerical values of precession, obliquity, and eccentricity to be expressed in trigonometrical form as quasiperiodic functions of time:

$$e \sin \tilde{\omega} = \sum P_i \sin(\alpha_i t + \eta_i) \quad [1]$$

Figure 1 Long-term variations over the last 400 ka and the next 100 ka of eccentricity, climatic precession, obliquity, and 65° N insolation at the summer solstice in WM^{-2} (Berger, 1978). This insolation is shown as an example of Milankovitch (1941) principles. It must be stressed that all latitudes and days are used in the LLN models. LLN, Louvain-la-Neuve.

$$\varepsilon = \varepsilon^* + \sum A_i \cos(\gamma_i t + \zeta_i) \quad [2]$$

$$e = e^* + \sum E_i \cos(\lambda_i t + \phi_i) \quad [3]$$

where the amplitudes P_i , A_i , E_i , the frequencies α_i , γ_i , λ_i and phases η_i , ζ_i , ϕ_i have been computed by Berger (1978; Berger and Loutre, 1991; <ftp://ftp.elic.ucl.ac.be/berger/berger78>). They can be used over a few millions of years, but for more remote times, numerical solutions are necessary (Laskar, 1999).

Over the past 3 million years, the orbit varied between near circularity ($e=0$) and slight ellipticity ($e=0.07$), with a quasi-period of about 400 ka over which a period of around 100 ka is superimposed. The periods of the most important terms in the series expansion of e are actually 404, 95, 124, 99, 131, and 2380 ka (in decreasing order of amplitude). The tilt of the Earth's axis of rotation varied between about 22° and 25° at a period of nearly 41 ka. Although this period corresponds in eqn [2] to the amplitude that is by far the largest, there are two other important terms with periods of 54 and 29 ka. As far as precession is concerned, two phenomena must be considered. The first is the axial precession. The second is related to the fact that the elliptical figure of the Earth's orbit is itself rotating counterclockwise leading to an absolute motion of the perihelion. The two effects together result in what is known as the climatic precession of the equinoxes, the equinoxes and solstices shifting slowly around the Earth's orbit, relative to the perihelion, with a mean period of 21 ka. This period actually results from the existence in eqn [1] of four periods that are close to 23 and 19 ka.

The long-term variations of these three astronomical parameters over the past show that their periods are not constant in time (Berger et al., 1998). The average period of climatic precession varies between 15 and 30 ka. For eccentricity, the time interval between two successive maxima averages ~ 95 ka, but it varies with the 400 ka cycle, being remarkably short when the eccentricity vanishes, as at 27 ka after present (AP) when the Earth's orbit will be circular. Actually, the most important theoretical period of eccentricity, 400 ka, is weak before 1 My BP, and is particularly strong over the next 400 ka, with the strength of the components in the 100-ka band changing in the opposite way. It is worth pointing out that this weakening of the 100-ka period started about 900 ka ago when this period began to appear very strongly in paleoclimate records. This implies that the 100-ka period found in paleoclimatic records is definitely not linearly related to eccentricity.

For obliquity, the main period is essentially stable, but there is an amplitude modulation with a time duration of about 1.3 My. The spectra of both the amplitude and frequency modulations of obliquity display significant power at 171 and 97 ka. Although the 97 ka is close to the so-called 100-ka eccentricity period, they are not related.

Obliquity defines the seasons: boreal (austral) summer occurs when the Earth's axis of rotation and its North Pole (South Pole) are tilted toward the Sun. An increase of obliquity increases the solar energy in high latitudes of the summer hemispheres, increasing therefore the seasonal contrast in both the northern and southern hemispheres. On the other hand, precession modulates the intensity of the seasons but acts at the world scale instead of at the hemispheric one. For

example, ~ 10 ka ago, the whole Earth received more solar energy during boreal summer and less during boreal winter because boreal summer occurred at perihelion and boreal winter at aphelion, leading to a maximum seasonal contrast in the NH. Today the winter solstice occurs near perihelion and the summer solstice at aphelion, leading to a minimum seasonal contrast in the NH. The magnitude of this seasonal contrast changes every half-precession cycle and is moreover affected by eccentricity. The elliptical shape of the Earth's orbit around the Sun affects, indeed, the Earth–Sun distance through the year. When the Earth is at perihelion, the distance is the shortest, equal to $(1 - e)$, when it is at aphelion, it is the largest, equal to $(1 + e)$. Consequently, the larger e , the larger the difference between these two extreme positions and in particular, the larger the seasonal contrast in the NH when boreal summer occurs at perihelion (see also Yin and Berger, 2012). Moreover, because the length of the seasons varies in time according to Kepler's second law, the solstices and equinoxes occur at different calendar dates during the geological past and future. Presently in the NH, the longest seasons are spring (92.8 days) and summer (93.6 days), while autumn (89.8 days) and winter (89.0 days) are notably shorter. In AD 1250, spring and summer had the same length (as did autumn and winter) because the winter solstice was occurring at the perihelion. The daily insolation is primarily a function of precession, except for the latitudes and days close to the polar night where obliquity dominates (but where the energy is close to zero). On the contrary, the total energy received during any time interval of the year defined in terms of the true longitude is only a function of obliquity (Figure 2; Berger et al., 2010). However, in this case, the length in days of such intervals varies in time as a function of precession only (Berger and Loutre, 1994), leading to an average irradiance being a function of both precession and obliquity. This spectral characteristic is also seen in the total irradiance calculated over a period of time defined in terms of the calendar (Figure 2).

Milankovitch Theory and Past Climates

Given the Milankovitch conditions for a glacial to occur, the northern high latitudes would remain cool enough in summer to prevent snow and ice from melting, and (as pointed out by Berger, 1980) mild winters would allow a substantial evaporation in tropical and temperate latitudes as well. As a consequence, abundant snow would fall in polar latitudes, the moisture being supplied there by an intensified general circulation due to an intensified latitudinal gradient.

A simple linear version of the Milankovitch model therefore predicts that the total ice volume and climate vary with the same regular pattern as the insolation. If this is true, the proxy record of climate variations would contain the frequencies of the astronomical parameters that are responsible for changing the seasonal and latitudinal distributions of the incoming solar radiation. Investigations during recent decades have indeed demonstrated that the 19-, 23-, and 41-ka periodicities actually occur in long records of Quaternary climate (Hays et al., 1976); that the climatic variations observed in these frequency bands are linearly related to the orbital forcing (Imbrie et al., 1992); and that there is a fairly consistent phase relationship between

Figure 2 Long-term variations from 400 ka BP to 100 ka AP of the total irradiation received at 65°N during June, July and August (blue curve) and during the period going from 70° to 160° in true longitude (Berger et al., 2010).

insolation, sea-surface temperature, and ice volume (Imbrie et al., 1984). Moreover, the geological observation of the bipartition of the precessional peak, a bipartition also found independently in astronomical computations by Berger (1977), was one of the first most delicate and impressive tests of the Milankovitch theory.

However, despite the evidence in support of the Milankovitch hypothesis, the same investigations identified the largest climatic cycle as 100 ka. As this eccentricity cycle is very weak in the insolation, it cannot be related to the orbital forcing by any simple linear mechanism (Imbrie et al., 1993). Actually, the variance components centered near this 100-ka cycle seem to be in phase with the eccentricity cycle, but its exceptional strength in the climatic record demands a nonlinear amplification.

The identification of the periodicities found in the geological records is, however, not always as clear. The 100-ka cycle, the most dominant feature in the ice volume record for the late Pleistocene, does not exhibit a constant amplitude over the past 2–3 million years; it disappears before 1 My BP, at a time when the ice sheets were much less extensive over the Earth (Prell, 1982). The SPECMAP (Spectral Mapping Project) group has also shown that the nature of the paleoclimate reconstructions and the phase lags between proxy records and the climate response to orbital forcing depend upon the location of the deep-sea cores and the nature of the climatic parameters under consideration (Imbrie et al., 1992, 1993; Ruddiman, 2003a; Ruddiman and Raymo, 2003).

Modeling Past and Future Climates

Since the publication of Hays et al. (1976), a number of studies have attempted to explain the relationship between

astronomical forcing and climatic change and some have tried to relate different forcing parameters to the ice volume. Among the first, Kukla (1972) suggested the use of latitudinal gradient of insolation. More recently, Shackleton (2000) showed that the glacial–interglacial ice cycles lag temperature, CO₂, and orbital eccentricity significantly. Another approach is to use climate models: both general circulation models and models that take into account the different components of the climate system (for a partial review of such experiments see Berger, 1995). These models aim to explain the response of the climate system to external forcings taking into account, as much as possible, the complexity of the main feedback mechanisms. These mechanisms include albedo and water vapor feedbacks, the continental biospheric impacts on high-latitude surface albedo, the altitude and continental effects on precipitation over the ice sheets, the lithospheric response to the ice-sheet loading, and the rheology (deformation and flow) of ice itself.

Sensitivity analyses have tentatively confirmed that the astronomical parameters act as a pacemaker of the glacial–interglacial cycles, the insolation forcing being able to induce them, but only under low CO₂ concentrations (Berger and Loutre, 2004). Long-term variations of CO₂ alone are not sufficient to drive glacial–interglacial cycles (Loutre and Berger, 2000a). When both insolation and CO₂ variations are used, it is significant that the model of Louvain-la-Neuve (LLN), in particular, simulates almost correctly the entrance into glaciation around 2.75 My BP, the late Pliocene–early Pleistocene 41-ka cycle, the emergence of the 100-ka cycle around 850 ka BP, and the glacial–interglacial cycles of the last 600 ka (Berger and Loutre, 2004; Figure 3 for 200 ka BP to 130 ka AP).

This glacial–interglacial cycle about 100-ka long is one of the most striking features of the Quaternary and is also linked to the future of our climate. As each cycle is

Figure 3 Simulated ice volume of the Northern Hemisphere using the two-dimensional LLN Northern Hemisphere climate model forced by insolation and CO₂ from 200 ka BP to 130 ka AP. The Vostok CO₂ concentration and Vostok scenario lead to the full line. The dotted line results from a simulation where CO₂ is kept equal to 210 ppmb over the next 130 ka, and the dashed curve provides the results of the 750 ppmv scenario. The ice volume increases downward (Loutre and Berger, 2000b). AP, after present; BP, before present; LLN, Louvain-la-Neuve; ppmv, parts per million by volume.

characterized by a long glacial period followed by a short interglacial (~10–15 ka long) and as our interglacial, the Holocene, is already 10 ka long, paleoclimatologists were naturally inclined to predict that the next Ice Age is quite close. Simulations using our climate model show, however, that the current interglacial will probably last much longer than any previous interglacial (Berger and Loutre, 2002) with an early entrance into glaciation being highly improbable. This is suggested to be related to the shape of the Earth's orbit around the Sun, which will be almost circular over the next tens of thousands of years. As this is primarily related to the 400-ka cycle of eccentricity, the best and closest analog for such a forcing is definitely Marine Isotopic Stage 11 (MIS-11), some 400 ka ago, not MIS-5e (Loutre and Berger, 2003). Modeling results with the LLN model (Berger and Loutre, 2002) and EPICA Community Members (2004) reconstruction confirm a similar behavior of the climate response during MIS-11 and MIS-1 with a length of 30 ka or more. An analysis of the interglacial modeling results (Yin and Berger, 2012) shows, however, that MIS-19 is an even better analog of MIS-1 than MIS-11. This is based on an analysis of the individual contributions of the greenhouse gas concentrations and insolation to the climate of the last 800 ka, showing that the latitudinal and seasonal distribution of insolation as well as the CO₂eq concentration of MIS-1 and MIS-19 are very much alike.

Because the latitudinal and seasonal distributions of insolation will not change significantly over the next tens of thousands of years, changes in greenhouse gas concentrations are expected to play an increasingly important role. This is particularly important in the context of the already exceptional present-day CO₂ concentrations (unprecedented over the past

1 million years) and, even more so, because of even larger values predicted to occur during the twenty-first century due to human activities (Houghton et al., 2001). According to experiments made with the two-dimensional LLN climate model, there seems to be a threshold in the CO₂ concentration (~700 ppmv) above which the Greenland ice-sheet melts and disappears totally within around 10 ka (Figure 3). Finally, sensitivity experiments using the LLN model show that only a CO₂ behavior similar to that which occurred during MIS-7 allows an early end of the present interglacial (Crucifix et al., 2005), thereby confirming that the anthropogenic greenhouse era might have begun thousands of years ago (Ruddiman, 2003b) but this is true only in this case.

However, many model refinements are still needed. For example, current models have still to explain why the variations of the oxygen isotope and EPICA records show a significantly lower amplitude before the mid-Brunhes event about 430 ka ago (Ganopolski and Calov, 2012; Yin and Berger, 2010), and why MIS-13 peak, according to Lisiecki and Raymo (2005), seems to respond to NH summer at aphelion rather than at perihelion.

From the mid-nineteenth century, the Quaternary has been considered synonymous with extensive glaciation of the mid-latitudes. Although there were local precursors, significant glaciation began in the late Oligocene (~35 My) in eastern Antarctica. It was followed by glaciation in mountain areas through the Miocene (in Alaska, Greenland, Iceland, and Patagonia), later in the Pliocene (e.g., in the Alps, the Bolivian Andes, and possibly in Tasmania), and in the earliest Pleistocene (New Zealand, Iceland, and Greenland). Today, evidence from both the land and the ocean-core sequences demonstrates that the major continental glaciations, outside the polar regions, were markedly restricted to the last 1 My–800 ka or less. This is not to say that glaciation did not occur earlier; indeed, glaciation limited to higher latitudes or mountain massifs certainly occurred throughout the 2.6 My of the Quaternary, particularly in the Rocky Mountains. It also occurred in eastern North America, in the Andes, and in southern Australasia. Indeed, evidence of extensive ice rafting, an indication that glaciers had reached sea level, is found from the earliest cold stage – the Praetiglian (2.6–2.4 My) and its equivalents, in both the North Atlantic and the North Pacific oceans (cf. [Haug et al., 2005](#)). Even earlier ice-rafted debris is found in ocean-sediment cores from the North Atlantic region, including the Barents Sea, and areas adjacent to Norway, N and SE Greenland, Iceland, and northern North America, and in the Southern Ocean off Antarctica.

Earth's climate, which had been extremely warm during the Cretaceous 'hot-house,' continued to be both warm and without extreme fluctuations during the Paleogene. An overall, long-term trend of cooling global climates through the Tertiary culminated in the mid-latitudes with warm temperate climates, alternating with cool-temperate climates in the Late Neogene. Like the later Neogene, the early Pleistocene (2.6–0.78 Ma) was characterized by climatic fluctuations dominated by the 41 ka precession cycle (see [Pliocene Environments](#)), during which relatively few cold periods were sufficiently cold and long to allow the development of substantial ice sheets. They include the Plio–Pleistocene boundary events marine isotope stages (MIS) 104, 100, and 98, together with early Pleistocene MIS 82, 78, 68, 60, 58, 54, 52, 36, 34, 30, and 26. Their content of heavy oxygen isotopes in the sea water ($\delta^{18}\text{O}_{\text{ocean}}\text{‰}$) reached values of ~4.6–5. These relatively high values suggest that major quantities of water might have been converted to ice sheets. It was not until the transition in dominant orbital cyclicity to the 100 ka cycles, which began ~1.2 Ma and was fully established by about 800 ka, that the cold periods (glacials) were regularly cold and long enough to allow ice-sheet development on a continental scale, outside the polar regions. Here, MIS 22 (~870–880 ka) was the first of the 'major' cold events that reached critical values of ~5.5 or above $\delta^{18}\text{O}_{\text{ocean}}\text{‰}$ equivalent to substantial ice volumes that typify glaciations of the

later Pleistocene (i.e., MIS 16, 12, 10, 6, and 4–2). Potentially, therefore, it would seem likely that there were a minimum of 20 periods during which extensive glaciation could have developed during the last 2.6 Ma, with the most extensive (~5–6 periods) being limited to the last 900 ka ([Figure 1](#)).

Precisely where these glaciations occurred and how far they extended is very difficult to determine, given that the remnants of less extensive early glaciation tend to be obliterated and mostly removed by later, more extensive advances. Although this is so in all terrestrial areas, it is especially difficult in mountain regions where the preservation potential of older sequences rapidly diminishes with time and subsequent glaciation. However, examination of the frequency of glaciation through the Cenozoic ([Figure 2](#)) indicates that glaciation in the Southern Hemisphere having been established first, principally in Antarctica and southern South America, has occurred continually from the Early Neogene to the present day. By contrast, Northern Hemisphere glaciation, although initially somewhat restricted, increased markedly at the Plio–Pleistocene boundary, increasing again in frequency in the latest early Pleistocene and reaching very high levels in the middle–late Pleistocene. While this pattern is not unexpected, potentially a result of the relative distribution of land and land-locked seas on the earth’s surface, the striking increase in ice sheets through the Quaternary clearly emphasizes that worldwide glaciation is in effect a Northern Hemispheric phenomenon.

Examination of the evidence accumulated in the INQUA project ‘Extent and Chronology of Quaternary Glaciations’ ([Ehlers and Gibbard, 2004a,b,c; Figure 3](#)), supported by other published sources, demonstrates the current state of knowledge. When examining the resulting tables ([Tables 1–3](#)), it is important to bear in mind that the stratigraphical control between regions, beyond the range of radiocarbon dating, is weaker than might be desired. This is particularly a problem outside Europe where biostratigraphy is less well developed and the sheer extent of the unexplored regions makes future discoveries likely. Thus, the presentation below can only be a first step toward a comprehensive overview. The correlations applied here are based on the Global Correlation Chart ([Gibbard et al., 2004, 2005](#)).

Europe

Evidence of glaciation is widespread across Europe and Siberia from throughout the Quaternary and indeed the Neogene ([Table 1](#)). However, before the middle Pleistocene, glaciation appears to be represented only by ice-rafted clasts, outside the mountain or high-latitude regions (e.g., in the Netherlands, lowland Germany, European Russia, and Britain). In this context, the Dutch ‘Hattem Beds’ of Menapian age (1–1.2 Ma; ? MIS 34–36) are of particular significance in that they indicate substantial glaciation of the Baltic region late in the early Pleistocene. Iceland is an obvious exception to this pattern, with glaciation in the mountains beginning in the Miocene (23.8–5.3 Ma BP; see [Coral Records of Relative Sea-Level Changes](#)) and occurring regularly through the Pliocene to the present day (cf. Greenland, below, [Table 2](#)). Likewise, in Norway, its adjacent offshore, and the neighboring Barents Sea, glaciation is recorded from the early Miocene, early Pliocene, and Plio–Pleistocene, and periodically throughout the

remaining period. The absence of evidence from the early middle Pleistocene probably represents destruction of evidence by later glaciation rather than an interruption of the glacial history.

In Italy, particularly in the northern mountains, glaciation is identified possibly from the Plio–Pleistocene onward but becomes established in the Dolomites by MIS 22 ([Muttoni et al., 2003](#)). Comparable evidence is also found from north of the Alps in Switzerland and southern Germany, with records even from the Pliocene in the former. However, in many cases, truly glaciogenic deposits are scarce or lacking, and in the absence of long, continuous sequences, dating is often problematic. Further to the west, in the Pyrenees, the oldest glaciation currently identified is of late Cromerian age (MIS 16 or 14).

The till sheets of the major glaciations of the ‘glacial Pleistocene’ (see [Mid-Quaternary in North America](#)) are found throughout Europe, and especially in the lowlands. Widespread lowland glaciation began in the early middle Pleistocene shortly after the Brunhes/Matuyama paleomagnetic reversal (780 ka). The phases represented include the Weichselian (Valdaian, MIS 4–2), Saalian (Dniepr and Moscovian, MIS ?8/6 and 6, respectively), Elsterian (Okan, ? MIS 12), and the Donian (Narevian, MIS 16). More limited glaciation may also have occurred in the circum-Baltic region during the latest early Pleistocene (MIS 20 and 22). It is curious, however, that evidence for glaciation in the early middle Pleistocene is absent from the North Atlantic and Norway, while it is certainly present in Denmark, the Baltic region, and European Russia.

There can be no doubt that at least two major glaciations occurred in Europe after the Eemian (MIS 5e) and prior to the Last Glacial Maximum (MIS 2). An early glaciation (probably MIS 5b) covered major parts of the West Siberian lowlands and blocked the drainage of the Ob and Yenisei rivers. Another extensive ice sheet (MIS 4) reached nearly as far east, while the Last Glacial Maximum was limited to the circum-Scandinavian region and the Putorana Plateau (see [Neoglaciation in the American Cordilleras](#)).

North America

The North American record of glaciation is similar to its European counterpart, the longest sequences being restricted to Alaska and the adjacent North-West Territories of Canada, which, together with Greenland and the Rockies, preserve evidence of glaciation from the Neogene to the present (see [Middle Pleistocene in Eurasia](#)) ([Table 2](#)). In northern Canada and Alaska, the oldest till and the accompanying ice-rafted detritus in marine settings date from the early Miocene, with regionally widespread glaciation occurring in the Pliocene and regularly throughout the Pleistocene (cf. [Haug et al., 2005](#)). In adjacent British Columbia, a comparable sequence is found, particularly in the north. Similarly, in Greenland, like Iceland ([Table 1](#)), ice caps with glaciers reaching the sea probably developed in the north from the middle Miocene (~14 Ma). By the late Miocene, inland ice shields were periodically present, especially in the mountainous east, with ice reaching the sea in SE Greenland, while contiguous ice sheets have occurred since the earliest Pleistocene (see [Transition from Late Neogene to Early Quaternary Environments](#)). Adapted from Ehlers J and Gibbard PL (2003) Extent and chronology of glaciations. *Quaternary Science Reviews* 22: 1561–1568.

United States, the eastern Rockies have a much shorter glacial sequence. Only from Montana and North Dakota is Pliocene-age till known, while in California, the glacial evidence begins at the Plio–Pleistocene boundary (MIS 98–104).

While evidence of early Pleistocene glaciation has been found in areas as distant as Pennsylvania, Wisconsin, and possibly Minnesota, widespread lowland glaciation is first seen again throughout the continent in MIS 22 (pre-Illinoian F),

immediately before the Brunhes/Matuyama paleomagnetic Chron boundary (cf. Europe, [Table 1](#)). From this point onward, major ice sheets are known to have covered large areas in the middle Pleistocene pre-Illinoian events during MIS 16 (D), 12 (B), 8 (A), and 6 (Illinoian *sensu stricto*) and the late Pleistocene MIS 2–4 (Wisconsinan) (see [Middle Pleistocene Glaciations in the Southern Hemisphere, Overview](#)). Evidence from East Greenland suggests that its quasi-permanent ice sheet may have

come close to disappearance during the Eemian Stage interglacial (ca. MIS 5e) (Funder et al., 2011).

South America/Antarctica

As already noted above, the glacial record of the extreme Southern Hemisphere is the longest in the world during the Cenozoic, with ice already having formed in the late Eocene–early Oligocene in East Antarctica and built up in a step-like pattern through the Neogene (Table 3). Minor ice recession occurred in the youngest Miocene, and considerable fluctuations occurred during the Pliocene. The present polar conditions were already established by the early Pleistocene after 2.5 Ma. Similar Neogene glaciation is known from the Piedmont areas of Argentina and Chile, where, like Antarctica, substantial ice caps were established by 14 My ago. Widespread lowland glaciation between 2.05 and 1.86 Ma (ca. MIS 68–78), followed by the so-called 'Initioglacial' or 'Great Patagonian Glaciation,' took place at 1.15–1.00 Ma (ca. MIS 30–34), with subsequent less extensive glaciation occurring repeatedly up to the present.

Further north, the earliest glaciation recorded in the Bolivian Andes dates from 3.27 Ma, with extensive events at 2.2 Ma (ca. MIS 82), etc. In Columbia, the record begins at 2.5 Ma, with glacial outwash sequences extending well into the Bogota basin. As in Europe and North America, glaciation increased in

intensity throughout the Andean chain from 800 ka to the present day (see [Neoglaciation in Europe, Transition from Late Neogene to Early Quaternary Environments](#)). In Central America, the longest record is from Mexico, where oldest moraines on volcanoes have been dated to 195 ka and probably relate to a pre-MIS 6 glaciation.

Central Asia

Because of the relatively late uplift of High Asia, glaciation of Tibet and Tianshu is not recorded before the middle Pleistocene, of which MIS 12 was the most extensive (Table 3). In Tianshu, older glaciation (?MIS 16) may also have occurred. Subsequent events took place during MIS 8, 6, and 4–2 and continue even today in the highest peaks (see [Late Quaternary in Highland Asia](#)).

Australasia

Glaciation in Australasia, apart from that on some high volcanoes in Papua and Indonesia, occurred in both Tasmania and New Zealand (see [Eustatic Sea-Level Changes Since the Last Glacial Maximum](#)) (Table 3). The earliest records in both islands are from the Plio–Pleistocene (2.6 Ma: MIS 98–104), although it may be older in Tasmania. Only slightly younger is

Table 3 Occurrence of glaciation in the rest of the world through the Cenozoic based on numbers of observations presented in contributions to the INQUA project 'Extent and Chronology of Quaternary Glaciations' (Ehlers, Gibbard and Hughes, 2011)

the oldest known glacial event in New Zealand (the Porika Glaciation). This is followed by a 1 My break before the glacial record continues in MIS 12, followed by MIS 6, 4, and 3. In Tasmania, an early middle Pleistocene event, possibly during MIS 16, is followed by glaciations during MIS 6 and 3.

Africa

The glacial record in Africa is restricted to the mountains of East Africa and the High Atlas (Table 3). On Mount Kilimanjaro, glaciation began at ~2.0 Ma (?ca. MIS 68), while a second glaciation is recorded before the Brunhes/Matuyama magnetic reversal. Younger glaciations appear to be broadly equivalent to those elsewhere, that is, during MIS 12, 6, and 2. There is evidence for probably three glaciations of the Atlas mountains, but their age remains equivocal at present. Very limited glaciation may also have occurred in South Africa (Hall and Meiklejohn 2011).

Introduction

Definition of the Plio-Pleistocene Boundary

As published by Pratt et al. (2009), a strong majority of International Commission on Stratigraphy voting members approved the proposal that the base of Pleistocene Series/Epoch, likewise the base of the Quaternary System/Period, and thus the Neogene–Quaternary boundary are lowered such that the Pleistocene now includes the Gelasian Stage/Age and its base is defined by the Monte San Nicola GSSP in Sicily. This base also defines the base of the Gelasian. With these definitions, the Gelasian Stage/Age is transferred from the Pliocene Series/Epoch to the Pleistocene (Gibbard et al., 2009).

Accordingly, the base of the Quaternary now occurs near the end of a stepwise long-term climatic deterioration, at 2.61 Ma, which is coeval with marine isotope stage (MIS) 104 and the Gauss–Matuyama geomagnetic boundary (Figure 1). The deterioration had started about 3.0 Ma, subsequent to interglacial MIS G17 and glacial MIS G12, and was linked to the onset of major Northern Hemisphere glaciation (NHG), in particular, on Greenland. This event formed a major tipping point in the long-term benthic oxygen isotope ($\delta^{18}\text{O}$) history of the Cenozoic (Lisiecki and Raymo, 2005; Zachos et al., 2001). By contrast, the top of the Gelasian at ~ 1.8 Ma, formerly used to define the base of the Pleistocene, did not correspond to any major event in the Earth's climate history. In these discussions, evidence from ocean sediments is dominant, because the necessary stratigraphic control relies heavily on $\delta^{18}\text{O}$ records that were measured on Foraminifera in pelagic and hemipelagic sediments.

This article discusses various potential forcings and causal chains that may have triggered the great change in global environment, known as the onset of the Quaternary. Many lines of evidence and argumentation are directly adopted from Sarnthein et al. (2009) after including various findings published more recently.

Conceptual Models that Try to Explain the Onset of Major NHG

The potential forcings for the onset of major NHG, in particular, for the buildup of a continent-wide ice sheet on Greenland and the associated planetary cooling, do not form a merely academic topic. Rather, the forcings present a burning question, because the scenario of the warm upper Pliocene that preceded a full glaciation of Greenland may serve as an analog for the uncertain Earth's future climate in view of global warming in terms of albedo, sea-level rise, and continental aridity and/or humidity (Dowsett et al., 2010; Haywood, 2009). A number of hypotheses tend to explain the potential forcings that may have controlled the onset of 'major' NHG, as summarized by Sarnthein et al. (2009) and Seki et al. (2010). Willenbring and von Blanckenburg (2010) strongly questioned the model of globally increased rates of weathering and erosion that have triggered a late Neogene drawdown

of atmospheric CO_2 and successive cooling. In this article, four other theories are discussed in the context of paleoclimatic data sets. With regard to glaciations, we need to stress the term 'major,' because minor, regional ice sheets have already been registered in the Northern Hemisphere, in particular on Greenland, since the late Eocene (Eldrett et al., 2007) and in particular, since the late Miocene, as summarized in Paleogeography volume 23/3 (2008) and by De Conto et al. (2008). However, the major rise in the discharge of ice-rafted debris (IRD) to the ambient seas, which suggests the beginning of Quaternary-style full glaciations, only occurred near 3.0–2.7 Ma, as first outlined by Shackleton et al. (1984) and displayed further below.

The role of orbital forcing

Mere changes in orbital forcing of climate may form general thresholds and thus act as potential mechanism to initiate the buildup of major NHG, first proposed by Maslin et al. (1996) and recently by several other authors. Indeed, the amplitudes of orbital obliquity cycles increased significantly from ~ 3.0 to 2.5 Ma. This trend closely paralleled a major increase in global ice volume, as recorded in the benthic $\delta^{18}\text{O}$ signal (Figure 1). However, the increase in the amplitudes of obliquity was reversible (at 2.25–1.8 Ma; Laskar et al., 2004), whereas the onset of major NHG was not or only reversible to a minor degree and thus cannot be properly explained.

Huybers and Molnar (2007) established a more sophisticated approach to test the potential influence of orbital forcing on the onset of major NHG. They calculated the number of positive degree days (PDD) for North America $>50^\circ$ N versus the equator, obtained by applying temperature perturbations at high latitudes, expected to result from tropical anomalies and orbital variations (Figure 2(b)). After ~ 4.2 Ma, the PDD number decreased gradually down to a lowstand that persisted after 1.8 Ma. This trend preceded the start of the long-term cooling of sea-surface temperatures (SST) in the eastern equatorial Pacific by ~ 0.5 My (Figure 2(a)); likewise, it preceded the buildup of major NHG by more than 1 My (Figure 2(c)). This time span requires an extremely long-lasting internal memory effect in the climate system, difficult to conceive, thus leading the authors to the honest conclusion: "Understanding the puzzle of what caused the eastern equatorial Pacific to cool off on a timescale too long to invoke the atmosphere–ocean–cryosphere system by itself now appears all the more pressing."

The role of the Indonesian gateway systems

Two hypotheses invoke as a cause for the onset of Quaternary-style climates: either a significant constriction or closure of major ocean gateway systems, the Indonesian and the (former) Panamian/Central American seaways (CAS), which are fundamental for the reallocation of heat and sea-surface salinity (SSS) among the different tropical oceans.

Figure 1 'LR04' benthic $\delta^{18}\text{O}$ record of global ice volume changes over the last 5 Myr (Lisiecki and Raymo, 2005; modified from Sarnthein M, Bartoli G, Prange M, et al. (2009) Mid-Pliocene shifts in ocean overturning circulation and the onset of Quaternary-style climates. *Climate of the Past* 5: 269–283). Transition from the Late Pliocene 'Golden Age' (2.9–3.4‰ $\delta^{18}\text{O}$) to Quaternary-style climates near 3.0–2.8 Ma. Note the variable $\delta^{18}\text{O}$ scales. The 'Golden Age' represents a state of small scale and fairly uniform climate oscillations that continued since 4.0 Ma, subsequent to a further 0.2–0.3‰ increase of cold $\delta^{18}\text{O}$ excursions only near 4.2–4.0 Ma in the middle early Pliocene. Numbers are marine isotope stages (MIS).

Cane and Molnar (2001) first proposed the gradual closure of the Indonesian seaways near 4 Ma as forcing important to set the stage for the onset of Quaternary-style climates. More precisely, they suggested that the northward plate-tectonic shift of the (previously little known) small and elongate island of Halmahera, northwest of New Guinea, finally barred the West Pacific Warm Pool (WPWP) from warming the Indonesian Throughflow (ITF) subsequently being fed by cooler subsurface waters from the subtropical Northern Pacific (Figure 3). On the other hand, near-surface heat export from the WPWP was then diverted to the northwest Pacific.

Karas et al. (2009) constrained a distinct cooling and freshening of subsurface waters in the Eastern Indian Ocean and, thus, of the ITF more closely, to 3.3–3.2 Ma, thus indeed suggesting a linkage to the onset of Quaternary-style climates. In particular, the progressive restriction of the ITF may have implied a cooling of West Indian equatorial surface and

upwelling waters and thus have reduced evaporation, which should result in a decrease in moisture of the African and Indian monsoon. However, East African lake records just reflect a reversed trend, a prominent lake maximum and humid event near 3.1 Ma (Trauth et al., 2005). Accordingly, the actual implications of the restriction of the Indonesian gateway system for large-scale climate change still need further clarification.

The Panama hypothesis

Various recent lines of evidence suggest direct linkages between the final closure of the CAS, more precisely at Panama, and several follow-up processes relevant to climate change in the North Atlantic, northern North Pacific, and Arctic Oceans (Sarnthein et al., 2009, and references summarized therein). The final closure of CAS presents the most recent plate-tectonic change of ocean configuration in geological history, an uplift process related to the subduction of the Galapagos aseismic

Figure 2 Model of Huybers and Molnar (2007, suppl.) on (b) North America's 'positive degree days' (PDD), compared with East Pacific cooling/temperature anomalies (Lawrence et al., 2006) (a), and the $\delta^{18}\text{O}$ record of growth of global ice volume (Lisiecki and Raymo, 2005) over the last 5 My (c). Vertical arrows mark major tipping points in climate records. The time span between the onset of reduced PDD and the end of the Pliocene 'Golden Age' amounts to >1 My. Modified from Sarnthein M, Bartoli G, Prange M, et al. (2009) Mid-Pliocene shifts in ocean overturning circulation and the onset of Quaternary-style climates. *Climate of the Past* 5: 269–283.

Figure 3 Location of the island Halmahera, today preventing the West Pacific Warm Pool from flowing into the Indonesian throughflow (Cane and Molnar, 2001). ridge (Meschede and Barckhausen, 2001). Weyl (1968) and Keigwin (1982) first proposed this event as potential forcing for the onset of Quaternary-style climates. On the basis of diverging nannofossil communities, Kameo and Sato (2000) first succeeded in pinning down the final closure of CAS to an age close to 2.76 Ma (MIS G6; equal to 2.73 Ma on the revised timescale LR04; Lisiecki and Raymo, 2005), a timing that indeed comes close to the onset of major NHG as first derived by Shackleton et al. (1984). The closure may have triggered a rise in both the poleward heat and moisture transports and in meridional overturning circulation (MOC) of the Atlantic, which in turn have resulted in a lowering of atmospheric $p\text{CO}_2$; thus, the above phenomena may have finally been responsible for the full glaciation of Greenland and for the numerous and gradually intensifying Quaternary-style glaciations in Laurentia and northern Eurasia.

Driscoll and Haug (1998) assessed in detail the causal chains of climate change linked to the 'Panama Hypothesis,' trying to reconcile the effects of two actually counteracting forcings, increased poleward heat and moisture transports for the buildup of a continent-wide ice sheet on Greenland. Driscoll and Haug postulated that stronger heating of the northern North Atlantic will result (1) in enhanced evaporation and moisture transport via the westerlies to northwestern Eurasia, as also displayed by the model of Lunt et al. (2007), (2) in an increased river discharge from Siberia to the Arctic Ocean, in turn leading to (3) enhanced sea-ice formation and (4) an increase in Arctic albedo, an important feedback factor, and, therefore, to (5) more favorable conditions for the growth of Northern Hemisphere ice sheets.

On the other hand, Molnar (2008) listed extensive doubts on the proposed linkages between closing CAS and the onset of Quaternary-style Ice Age climates. In particular, he was concerned about the proposed late Pliocene age of the closure and the possibility of establishing an approximate simultaneity between the closure and the first major ice advance. Moreover, he challenged the feasibility of reconstructing a precise record of the progressive and final closure of CAS. Notably, he stressed the uncertainties in deriving the closure from an increase in (sediment proxy-based) SSS differences between the Caribbean and the eastern Equatorial Pacific. Also, he doubted the reliability of conclusions deduced from sediment records of concurrent low- and high-latitude changes. Finally, he pointed out the apparently differential evidence simulated by different general circulation models. In this article, we need to handle these questions with care.

The role of a decline in atmospheric CO_2

On the basis of a coupled general circulation model, Lunt et al. (2008) made a strong argument that a decline in the late Pliocene atmospheric CO_2 content from 400 to 280 ppmv needs to cause the buildup of major NHG at the onset of the Quaternary (Figure 4). This decline in $p\text{CO}_2$ did not affect the precipitation patterns over Greenland and the ambient sea regions but triggered a significant decrease in surface temperatures by 2–3 °C all over Greenland, thus promoting major ice growth. None the less, the origin of that reduction in the greenhouse effect still awaits a concise explanation.

Until recently, the CO_2 hypothesis suffered from the problem that published (marine and terrestrial) sediment records

provided hardly any satisfying evidence for the postulated late Pliocene drop in atmospheric CO_2 . Seki et al. (2010) now succeeded in generating two pertinent and strongly parallel high-resolution CO_2 records on the basis of two independent proxies in a tropical marine sediment core: (1) boron isotopes ($\delta^{11}\text{B}$) measured on the planktic surface dweller *Globigerinoides ruber* and (2) $\delta^{13}\text{C}$ of long-chain alkenones of haptophyte algae and planktonic Foraminifera calcite (ϵ_{p37-2}), values that were corrected for differential coccolith growth sizes. Both records reflect a Pliocene CO_2 level of 300–370 ppmv from ~4.9 to 3.1 Ma (Figure 4), which indeed slightly exceeded the preindustrial CO_2 level of 285 ppmv, characteristic of Quaternary interglacials. However, with the first onset of climatic deterioration after 3.1 Ma (MIS K1), the CO_2 values did not fall but rise markedly up to >400 ppmv – a prominent CO_2 maximum that terminated with a sudden drop near 2.85 Ma (immediately prior to MIS G10). This drop marked the onset of a largely constant CO_2 plateau at ~250–290 ppmv, characteristic of Quaternary interglacials.

These CO_2 records leave us with the open question as to which kind of change in the global carbon reservoirs, more specifically, which changes in ocean MOC, may have actually caused the fairly abrupt short-term rise and drop in atmospheric CO_2 during the latest Pliocene, that finally introduced the subsequent long-lasting CO_2 low of the Pleistocene. The CO_2 changes then may have served as a major amplifier mechanism of climate change, possibly similar to the CO_2 oscillations recorded for the orbital-scale climate changes of the last 400 ka (Kawamura et al., 2007). A top candidate mechanism to induce the outlined CO_2 changes may be linked to the final closure of the CAS, which triggered major changes in both the Atlantic MOC (AMOC) and a largely persistent sea-surface stratification of the subarctic North Pacific (Sigman et al., 2004), as outlined further below.

Final Closure of CAS as Trigger for the Onset of Quaternary Climates

Models, Concepts, and Implications

Maier-Reimer et al. (1990) first employed an ocean general circulation model to simulate the potential impact of the closure of CAS on ocean circulation and climate. Accordingly, the closure stopped the incursion of Pacific low-salinity and nutrient-enriched surface waters, diluting West Atlantic SSS in the Caribbean, here inducing a profound rise in poleward heat and salt transport and, in turn, an enhanced AMOC. Later, various more advanced general circulation model (GCM) tests basically confirmed these findings (e.g., Murdock et al., 1997). Schneider and Schmittner (2006) focused on testing the role of four subsequent Panamaian sill depths from –2000 up to 0 m in SSS and SST distributions in the adjacent sea regions. Different from previous concepts (Haug et al., 2001), they found that major Pacific-to-Atlantic contrasts in SSS at 50–125-m water depth emerged only at gateway sill depths of less than 500 m, whereas a barring of intermediate waters between 2000 and 700–500 m gateway depth did not produce this change. At sill depths of 300–250 m, only one-third of the final contrast in SSS was established, whereas at 130 m, two-thirds of the final contrasts

Figure 4 Plio-Pleistocene growth of Greenland ice sheet (a), merely induced by a decline in atmospheric $p\text{CO}_2$ from 400 to 280 ppmv (model simulation of Lunt et al., 2008). (b) $p\text{CO}_2$ evolution at tropical ODP Site 999 (modified from Seki O, Foster GL, Schmidt DN, Mackensen A, Kawamura K, and Pancost RD (2010) Alkenone and boron-based Pliocene $p\text{CO}_2$ records. Earth and Planetary Science Letters 292: 201–211), based on *G. ruber* boron isotope ($\delta^{11}\text{B}$) data, derived pH with $(\text{CO}_3^{2-})_{\text{modeled}}$ (blue diamonds), or modern total alkalinity (red cycles), and (c) based on alkenone-based estimates determined using ε_{p37-2} values with a size correction (red closed and open squares for $b=90$ and 108, respectively). (d) Growth of global ice volume reflected by global stacked benthic $\delta^{18}\text{O}$ record LR04 (Lisiecki and Raymo, 2005). (e) Salinity gradient between Caribbean and East Pacific, based on the $\delta^{18}\text{O}$ difference in surface waters (for further explanations, see Figure 7). Final full closures and a reopening of CAS are coeval with distinct drops and rises in atmospheric CO_2 and, finally, with glacial MIS G10.

in SSS (i.e., 1.2 psu) were already established (Figure 5). Accordingly, only the closing of the topmost 250–130-m depth of the Panamaian gateways finally turned out to be crucial for triggering major changes in AMOC and, thus, in the storage capacity of CO_2 in the sea and, accordingly, in climate.

The coupled and fully dynamic models of Klocker et al. (2005) and Lunt et al. (2007) in part confirmed the conceptual model of Driscoll and Haug (1998), claiming that the closure of Panamaian seaways led to a warming of the central-to-northern North Atlantic (Figure 6), more intense Atlantic thermohaline

circulation, and enhanced precipitation over Greenland and the Northern Hemisphere continents. On the other hand, these models suggest that these forcings in total were too small by an order of magnitude to overcome the coeval warming and produce the observed major ice-sheet growth that marked the onset of the Quaternary. Consequently, modelers stressed a necessary linkage to a significant decline in atmospheric CO_2 , as recently corroborated by Seki et al. (2010). However, the characterizations of the sea-ice albedo and the sea-ice rheology employed may present potential flaws in the model studies of Lunt et al. (2007, 2008; more details in Sarin et al., 2009).

Figure 5 Impact of shoaling Panamanian seaways on Caribbean and equatorial east Pacific upper ocean salinities in a high-diffusion (HD) experiment with the UciV-ESCM model (Sarnthein et al., 2009; Schneider and Schmittner, 2006). (a) Model data for different sill depths plotted on vertical transect and map. (b) Increase in East-Pacific-to-Caribbean Sea-surface salinity (SSS) contrasts at 50–125 m water depth (w.d.) over different sill depths, deduced for waters ambient to Sites 999 and 1241 (site locations in Figure 8), and resulting increase in NADW flow, assuming a largely linear relationship with changes in SSS contrasts. Modified from Sarnthein M, Bartoli G, Prange M, et al. (2009) Mid-Pliocene shifts in ocean overturning circulation and the onset of Quaternary-style climates. *Climate of the Past* 5: 269–283.

Sediment Records on the Final Closing of CAS

The model-based SSS differences between the Caribbean and eastern Equatorial Pacific start to rise as soon as the Panamian sill depth has dropped to less than 250–300 m (Figure 5), here defined as impact of the final closure of the Panama seaways. The postulated rise in salinity anomalies of the mixed surface layer (at 40–80-m water depth; Steph et al., 2006) can be traced in continuous sediment records obtained from Ocean Drilling Program (ODP) sites 999 and 1241, immediately northeast and southwest of the Panama Isthmus (Bartoli et al., 2005; Groeneveld, 2005; Groeneveld et al., 2006). The records indeed show a major increase in the anomalies of sea water $\delta^{18}\text{O}$ over the late Pliocene, which reflects the expected rise in SSS differences (Figure 7).

The thermocline of the tropical Eastern Pacific was subject to a major shoaling already as early as 4.5–4.0 Ma (Steph et al., 2010). In contrast, the interoceanic SSS differences between the southwestern Caribbean and eastern Pacific remained close to zero until after 4 Ma. First but still reversible rises in the SSS gradient of the mixed layer occurred only near 3.75 and 3.5–3.3 Ma, when the gradient reached up to 0.5 psu and more. At 3.16 Ma (MIS KM3) it reached for a first time >0.8–1.0 psu. These short-lasting precursor signals of a major shallowing and/or closure of the Panama seaways may in part reflect short-term volcano-tectonic events and in part orbital ice and sea-level cycles. A largely irreversible SSS contrast began only after 2.95 Ma

(after MIS G17) and finally, at 2.6–2.5 Ma, when the difference values came close to the model-predicted SSS anomaly maximum. The latter two events suggest a final two-step closure of the shelf seaway induced by the uplift of the Panama Isthmus. At that time, the uplift factor obviously dominated any other superimposed orbital-scale sea-level fluctuations, which is also shown in Figure 7. Irrespective of some possible early diagenetic influences on the underlying Mg/Ca data (Groeneveld et al., 2008), the outlined record of SSS anomalies has a great advantage over various previously published discontinuous and in part poorly dated marine and biostratigraphical evidence on the closure of the Panama Isthmus (Molnar, 2008). This is particularly because of the clear orbital age control and the close resemblance to the modeled SSS trends (Figure 5). Various lines of land-based evidence from Panama likewise document a first full closure of the seaway, which occurred near 2.85 Ma only (Coates et al., 2004, and oral communication).

Northern Ocean Response to the Closing of CAS

North Atlantic Sediment Records Reflecting the Onset of Major NHG

Model-based evidence (Klocker et al., 2005; Lunt et al., 2007) suggests that the final closure of the CAS necessarily led to two counteracting climatic forcings with an opposite effect on

Figure 6 Changes in surface temperatures (a) and precipitation (b), obtained by comparing closed Panamanian seaways with open seaways (model experiments of Lunt et al., 2007). From Sarnthein M, Bartoli G, Prange M, et al. (2009) Mid-Pliocene shifts in ocean overturning circulation and the onset of Quaternary-style climates. *Climate of the Past* 5: 269–283.

high-latitude glaciation in Greenland (Figure 6). On the one hand, the closure strengthened the poleward heat transport that implied enhanced glacial melt. On the other hand, it promoted the poleward transport of atmospheric moisture to northern Eurasia, a freshening of the Arctic Ocean, and a series of consequential changes that resulted in snow and ice accumulation. Indeed, various sediment records from the northern North Atlantic provide independent evidence for

both transport processes and their linkages to the onset of major NHG together with the Neogene–Quaternary boundary.

The onset of major NHG is best documented at ODP Site 907 to the east of Greenland and the East Greenland Current (EGC; Figures 8 and 9). This position is ideal for monitoring the discharge of IRD from icebergs coming from northeast Greenland and the Arctic Ocean. A second IRD record measured at IODP Site 1307 near the southern tip of Greenland

Figure 7 Late Pliocene increase in sea-surface salinity gradient between Caribbean (CAR) and eastern equatorial Pacific, based on paired *Globigerinoides sacculifer* Mg/Ca and $\delta^{18}\text{O}$ data for depth habitats of 40–80 m (records of Groeneveld, 2005; Steph et al., 2006). Modified from Sarnthein M, Bartoli G, Prange M, et al. (2009) Mid-Pliocene shifts in ocean overturning circulation and the onset of Quaternary-style climates. *Climate of the Past* 5: 269–283. A $\delta^{18}\text{O}_w$ gradient of 0.6–0.7‰ (hatched line; uncertainty of $\sim 0.07\text{‰}$ for the 10-point running mean of $\delta^{18}\text{O}_w$) equates to a SSS gradient of 1.2–1.8 psu, which corresponds to a full closure of CAS according to the modeled gradients shown in Figure 5(a). Age scale comes close to LR04 (Lisiecki and Raymo, 2005). Small letters and numbers at SSS gradient record (98/100, G6, etc.) label marine isotope stages.

Figure 8 Deep Sea Drilling Project (DSDP), Ocean Drilling Program (ODP), and Integrated Ocean Drilling Program (IODP) site locations used in this article and various surfaces (warm, red; cold, blue) and deepwater currents (broken lines) in the North Atlantic and North Pacific.

Figure 9 Closure of CAS (increasing $\delta^{18}\text{O}_{\text{sw}}$ differences between eastern tropical Pacific and southwest Caribbean, inverted from **Figure 7**) versus exponential changes in ice-rafted debris (IRD) at Site 907 (Bartoli et al., 2005; Jansen et al., 2000) and Site 1307 (plotted for two alternative age models) and the stacked benthic $\delta^{18}\text{O}$ record LR04 of global ice volume (Lisiecki and Raymo, 2005; small letters and numbers label marine isotope stages 104 – MG8). IW, intermediate water. The great IRD increase at Site 907 3.2–3.12 Ma matches a major cooling and freshening of the East Greenland Current (age model 1), shown in **Figure 12**. Modified from Sarnthein M, Bartoli G, Prange M, et al. (2009) Mid-Pliocene shifts in ocean overturning circulation and the onset of Quaternary-style climates. *Climate of the Past* 5: 269–283.

(**Figure 9**; Sarnthein et al., 2009) also includes IRD originating from mountain glaciers calving nearby into the Scoresby Sound and from southeast Greenland. Accordingly, IRD changes at Site 907 (Bartoli et al., 2005; Jansen et al., 2000) may best display the long term and major trends in the evolution of NHG, whereas IRD changes at Site 1307 rather reflect interesting aspects of short-term orbital-scale climate variability in southern Greenland. For comparison, the first IRD was deposited at the northeast Atlantic Site 552A to the west of Ireland at MIS G6, 2.72 Ma (Shackleton et al., 1984), approximately 110 ka prior to the official base of the Quaternary, defined at 2.61 Ma.

In harmony with the model of Driscoll and Haug (1998), the suite of changes in IRD at Site 907 from 3.4 to 2.6 Ma followed a closely similar suite of distinct steps in the evolution of CAS with great detail and a persisting lag of ~ 40 ka (**Figure 9**). This linkage applied, for example, to the closing

and opening events at 3.24–3.16, 3.13–2.97, and 2.96–2.87 Ma, except for the final episode of CAS closure after 2.7 Ma, when a major Greenland ice sheet had already preexisted from a preceding buildup. Each closing or opening of the CAS directly involved an exponential rise or drop in IRD abundance, respectively, with a final IRD extreme at MIS G10, 2.82 Ma.

However, the outlined coherence and phase lags of the IRD and CAS records alone do not yet provide adequate evidence to derive the origin of major NHG. Certainly, the persistent lag of changes in IRD may reflect significant but reasonable memory effects in the climate system. Moreover, the lags show that the oscillations in the buildup and melt of continental ice volume and resulting eustatic sea-level variations cannot have primarily controlled the closing events of CAS. Conversely, the CAS events need to have influenced the variations in IRD supply, in a way to be explored.

Figure 10 Closings of CAS ($\Delta\delta^{18}\text{O}_{\text{sw}}$ record inverted from [Figure 7](#)) and Plio-Pleistocene warmings at North Atlantic Sites 984 and 609 (based on Mg/Ca data; [Bartoli et al., 2005](#)), Site 982 (based on U^{37} ; [Lawrence et al., 2009](#), age scale modified and suppl. by [Khelifi et al., 2012](#)), and Site U1313 (based on U^{37} ; [Naafs et al., 2010](#)). Orbital age control of SST records may in part be slightly improved. Site locations are shown in [Figure 8](#).

Sediment Records of Increased Poleward Heat Transport, AMOC, and CO_2 Drawdown in the Ocean

Four continuous SST records with millennial-scale resolution were published from late Pliocene to early Pleistocene sediment sections in the northeastern and central North Atlantic ([Figures 9 and 10](#)); two of them were derived from Mg/Ca ratios of planktic foraminifers (S. 984 and S. 609) and two from the alkenone organic proxy Uk^{37} (S. 982, S. U1313). As predicted by modeling, all four SST records likewise reflect long-term coeval warmings and coolings. Each of them presented an increase or decrease in the poleward heat transport with the North Atlantic and

Irminger currents, coeval with an event of full closing or renewed opening of the CAS. For example, a distinct overall rise in SST by 2–3 °C occurred from 3.25 to 3.16 Ma and from 3.0/2.95 to 2.85/2.78 Ma, and conversely, a 4 °C drop occurred from 3.15 to 3.02 Ma. Each of these warmings and coolings includes up to four orbital-scale SST oscillations. The final closure at 2.73 Ma also induced a complete shut-down of the advection of nutrient-enriched surface waters from the eastern tropical Pacific to the North Atlantic, which in turn led to an abrupt productivity drop in the northern North Atlantic (reflected by the sudden appearance of the benthic foraminifer *Cassidulina teretis*; [Bartoli et al., 2005](#)).

Figure 11 Closure of CAS ($\Delta\delta^{18}\text{O}_{\text{sw}}$ record inverted from [Figure 7](#)) and increased Atlantic MOC deduced from decreasing Mg/Ca-based bottom water temperatures at Site 609 and rising benthic $\delta^{18}\text{O}$ values at sites 609 and 610, suggesting a rise in deepwater density ([Bartoli et al., 2005](#), and references cited therein). Small letters and numbers (101–M1) label marine isotope stages. Age scale tuned to [Tiedemann et al. \(1994\)](#), coming close to LR04 ([Lisiecki and Raymo, 2005](#)). Site locations are shown in [Figure 8](#). Modified from [Sarnthein M, Bartoli G, Prange M, et al. \(2009\)](#) Mid-Pliocene shifts in ocean overturning circulation and the onset of Quaternary-style climates. *Climate of the Past* 5: 269–283.

Each warming of the North Atlantic Current matched an increase in SSS by 0.2–0.4 psu, as inferred from paired planktic $\delta^{18}\text{O}$ and Mg/Ca-based SST values ([Bartoli et al., 2005](#)). Accordingly, each closing of CAS, and in particular, the most effective closure at ~3.0–2.85 Ma, resulted in a significantly intensified convection of deepwater in the Nordic and Labrador Seas. The strengthened AMOC is reflected by a series of proxies, a coeval long-term temperature drop (–1.5 and –2 °C), and a slight rise in salinity and density (increased benthic $\delta^{18}\text{O}$ values) of deepwaters. In particular, it is suggested by a distinct rise in deepwater ventilation, which is documented by a 0.3‰ increase in the short-lasting interglacial maxima in epibenthic $\delta^{13}\text{C}$ at Sites 609 and 610 at 2400–3880-m water depth, that is, the core depth of North Atlantic Deep Water (NADW; [Bartoli et al., 2005](#); [Figure 11](#)). The rise in NADW ventilation at 3.0–2.85 Ma followed an earlier, similar rise interpreted for 4.7–4.0 Ma ([Steph et al., 2010](#)). From 2.8 to 2.73 Ma, however, the interglacial $\delta^{13}\text{C}$ values dropped back to the level prior to 3.0 Ma.

In summary, the outlined changes in North Atlantic circulation and hydrography clearly parallel the twofold exponential rise in IRD at Site 907 ([Figure 9](#)), which forms the onset of persisting high IRD contents and hence marks best the onset of

major NHG and Quaternary-style climates, in particular at 2.93–2.82 Ma (MIS G10). The parallel change of these records strongly suggests a close causal linkage between the buildup of a continental ice sheet on Greenland and an enhanced MOC.

Finally, the latter change was tied to a coeval significant reduction in atmospheric CO_2 , as displayed in two, independently generated CO_2 records ([Seki et al., 2010](#); [Figure 4](#)). Although still coarse, their ~100-ka resolution is sufficient to trace some distinct ups and downs in $p\text{CO}_2$ from 3.15 to 2.75 Ma, which indeed have directly paralleled the renewed opening and closing of the CAS and the coeval drops and rises in IRD deposition, SST, NADW temperatures, density, and ventilation and, thus, in MOC intensity. Since Atlantic deepwater formation provides a major ocean sink for atmospheric CO_2 ([Takahashi et al., 2009](#)), the close linkage between the final openings and closings of the CAS, acting as trigger, and the differential exchange between the oceanic and atmospheric CO_2 inventories becomes obvious. This link may finally have promoted an accelerated buildup of the ice sheet on Greenland, a conceptual model that needs further quantification by physically based modeling and awaits a further extension of the high-resolution CO_2 records over the interval 3.1–4.5 Ma. Once established, the continent-wide ice sheet developed a

long-lived climatic memory effect capable of bridging any further short-lasting orbital-scale reopenings of the CAS and changes in MOC intensity subsequent to MIS G10 (Figures 9 and 11).

Haug et al. (1999) and Sigman et al. (2004) outlined a further factor possibly highly important for the late Pliocene reduction in atmospheric CO₂, the two-step onset of massive surface stratification in the subpolar North Pacific, induced by the two-step incursion of low-saline surface waters at 2.85 and 2.73 Ma. This feature may have impeded the upwelling and outgassing of CO₂-enriched intermediate and deepwaters and persisted over most of the Quaternary Period. However, the initial trigger, that is, the origin of a major increase in the freshwater discharge to this sea region, still awaits explanation, a question that is discussed below.

Sediment Records of Strengthened Poleward Freshwater Transport

Model simulations (Klocker et al., 2005; Lunt et al., 2007) suggest that the closure of Panamayan seaways led to a minor increase in precipitation all over the Northern Hemisphere, in particular, over East Greenland, the northeastern North Atlantic, western and central Europe, and the Kuroshio Current in the northwest Pacific (Figure 6(b)). Today, the EGC and its low SSS of 32–33 psu and temperatures near 0 °C provide a summary record of the outflow of low-saline surface waters from the Arctic Ocean into the northwestern North Atlantic. Here, IODP Site 1307 occupies an ideal position off the southern tip of Greenland to monitor past changes in the EGC and its source region, the Arctic Ocean, including the postulated events of a late Pliocene freshening and cooling to test the ‘Panama Hypothesis.’

The Panamayan seaways closed for a first time around 3.2–3.16 Ma, although only for a short time, and reopened later. The sediments at Site 1307 indeed show a clear response to this closure, recording a significant and long-term change in the composition of EGC waters between 3.22 and 3.02 Ma (Figure 12; details of age control in Sarnthein et al., 2009). During that time, both SST maxima and minima decreased by 6 °C, synchronous with a major SSS drop by ~2 psu, as deduced from a 1‰ decrease in δ¹⁸O of subsurface waters (assuming that the depth habitat of the planktonic foraminifer *Neoglobobulimina atlantica* was equal to that of the modern species *N. pachyderma* s). The immense cooling, freshening, and density drop of the EGC greatly exceed the increase in poleward atmospheric moisture transport predicted by models (Klocker et al., 2005; Lunt et al., 2007). The freshening of the EGC led necessarily to an enhanced stratification of the northwesternmost North Atlantic and more instability of AMOC. Thus, it introduced a new ‘Quaternary’-style regime of the EGC at S. 1307, documented until 2.7 Ma (Figure 12). Note that the EGC freshening clearly preceded the main decrease in atmospheric CO₂ at 2.85–2.73 Ma by at least 0.3 My. Rather, it paralleled a major but short-lasting CO₂ rise, possibly the result of a transient reduction in AMOC intensity.

The pronounced freshening of the EGC at 3.22–3.02 Ma provides an immediate record of Arctic Sea-surface conditions and, thus, evidence for a coeval substantial expansion of perennial Arctic sea-ice and enhanced albedo, conditions that were crucial for promoting the onset of NHG as result of the

full closure of CAS. The EGC-based evidence concurs with that of an Arctic diatom record (Herman, 1974, cited in Stein, 2008) but is opposed to some low-resolution Arctic sediment records (e.g., Frank et al., 2008) that suggest a much earlier date for the onset of perennial Arctic sea-ice.

Linkages to Changes in North Pacific Oceanography

Obviously, the late Pliocene rise in poleward freshwater transport has by far overcompensated the coeval effect of the enhanced poleward heat transport. Until recent times, the question as to where the freshwater flow of the EGC actually originated from remained unsolved. The outlined modest rise in atmospheric poleward moisture transport, which GCM models suggest for vast parts of the Northern Hemisphere after a closure of the CAS (Figure 6(b)), indeed strengthened the runoff into the Arctic Sea. However, this increase appears by far too modest to explain the great freshening of the EGC and the distinct climatic changes that induced the onset of a major glacification of Greenland (Lunt et al., 2007, 2008).

Thus, we need to search for a more substantial forcing mechanism to explain the striking SST/SSS drop from MIS KM3 to G21. Recent model studies (Motoi et al. 2005; Steph et al., 2006; Prange in Sarnthein et al., 2009) suggest that the late Pliocene evolution of the hydrology in the subarctic North Pacific as result of the final closure of the Panamayan seaways should be inspected more closely. Both Prange’s simulation with the NCAR Community Climate System Model (CCSM2/T31x3a) and that of Motoi et al. agree that the termination of the Panamayan throughflow (originally possibly amounting to 12 Sv; Steph et al., 2006) implied a major buildup of a freshwater cap in the northern North Pacific. Here, it resulted in an enhanced stratification (Sigman et al., 2004) and a rise of the steric height by 15 cm, whereas the steric height of the North Atlantic dropped by 20 cm.

In total, these changes implied a doubling of the low-saline Arctic throughflow (~1 Sv today) from the North Pacific through the Bering Strait up to the EGC, then strongly intensified, when assuming a Holocene sea-level stand (Figure 13). During the late Pliocene interglacials (prior to MIS G10), it was possibly up to 35 m higher than that today, and during glacials, it was hardly more than 20 m lower (Dowsett et al., 2010).

The sediments of ODP Site 882 provided some first records that indeed reflect parts of the model-predicted late Pliocene freshening and increased stratification of surface waters in the subarctic Northwest Pacific. Two paired planktic δ¹⁸O records show an overall 1‰ decrease for surface and subsurface waters from 2.85 to 2.75 Ma (Maslin et al., 1996). This shift hardly reflects a 4° warming but rather a 2-psu freshening from MIS G12 to G7, an interval well known for a general cooling of the Northern Hemisphere (Figure 1) and coeval with the great drop in atmospheric CO₂ (Figure 4). Swann (2010) established a first record of SSS at the same Site 882 on the basis of δ¹⁸O of diatoms. It shows a distinct SSS drop by 3 psu a little later, at 2.75–2.7 Ma, but does not extend back beyond 2.85 Ma. Further, indirect evidence for a freshening and significantly enhanced stratification, which implies a suppressed North Pacific outgassing of CO₂, came from the pronounced two-step decrease in diatom productivity at ~3.0 and 2.72 Ma (Haug et al., 1999). However, no paleosalinity record was generated yet for the interval 3.2–3.0 Ma, which was crucial

Figure 12 Closure of CAS ($\Delta\delta^{18}\text{O}_{\text{sw}}$ record inverted from Figure 7) (a) and stacked benthic $\delta^{18}\text{O}$ record LR04 of global ice volume (Lisiecki and Raymo, 2005; small letters and numbers label marine isotope stages 104 – MG8) (b) versus major subsea-surface temperature (SST) and salinity (SSS) drops of the EGC at Site 1307, 3.5–2.7 Ma, displayed for age models 2 and 1 (c) (Sarnthein et al., 2009). Sub-SST estimates are based on the Mg/Ca ratio of planktic subsurface species *Neogloboquadrina atlantica*. Two-psu shift in SSS is derived from a 1‰ shift in $\delta^{18}\text{O}_{\text{sea water}}$ ($\delta^{18}\text{O}_{\text{sw}}$; i.e., the $\delta^{18}\text{O}_{\text{carbonate}}$ record of *N. atlantica* after correction for SST), using a conversion factor of 1:2 as for modern EGC water. Modified from Sarnthein M, Bartoli G, Prange M, et al. (2009) Mid-Pliocene shifts in ocean overturning circulation and the onset of Quaternary-style climates. *Climate of the Past* 5: 269–283.

for testing the actual origin of the great freshening of the EGC at that time and thus remains a prime target for future studies.

Once low temperatures and low salinity of the EGC had been established, this current led to a robust thermal isolation of East Greenland from the counteracting poleward heat

transport further east through the North Atlantic and Norwegian currents. Over the last 3 My, the EGC formed an effective barrier to promote the growth of continental ice. Low-resolution ocean models may have problems in resolving this feature. Nevertheless, the simulations of Prange with the NCAR model indeed

Figure 13 Doubled flow rate of low-saline surface waters through the Bering and Fram straits ('Arctic throughflow') as a result of the difference between two equilibrium model runs, one with closed and the other with open CAS (assumed sill depth of 800 m and aperture of ~200 km); both models are forced by modern boundary conditions (NCAR Community Climate System Model 2, version T31x3a; M. Prange in [Sarnthein et al., 2009](#)). Modified from Sarnthein M, Bartoli G, Prange M, et al. (2009) Mid-Pliocene shifts in ocean overturning circulation and the onset of Quaternary-style climates. *Climate of the Past* 5: 269–283.

show that an enhanced EGC led to a year-round regional cooling over Central and South Greenland by up to 2 °C and strengthened annual snowfall in South Greenland, while almost the entire Northern Hemisphere became warmer in response to the CAS closure.

The Greenland continental ice sheet, once established, strengthened the Greenland High and, in particular, northerly winds along its eastern margin (cf. [Toniazzi et al., 2004](#)), which in turn further strengthened the EGC flow. This positive feedback, a kind of long-term memory effect, may have been crucial in keeping the low-salinity and cold regime of the EGC going over interglacial stages K1, G21, and G19, when the CAS was shortly reopened until the renewed and final closure after 2.95 Ma ([Figure 12](#)). From this time on, pronounced northerly winds along the East Greenland coast were strong enough to drive a vigorous EGC that pushes the polar front across Site 1307, similar to today.

In summary, it appears that the actual ties between the full closure of CAS and the onset of a Quaternary-style NHG were finally established by two independent forcing mechanisms linked to the great increase in the subarctic North Pacific freshwater cap: (1) It probably promoted the reduction in atmospheric CO₂, in addition to the enhanced CO₂

drawdown by the increase in AMOC. (2) This cap, in turn, significantly strengthened the low-saline Bering Strait and Arctic throughflow, previously overseen ([Molnar, 2008](#)). This flow was far more effective for the poleward advection of moisture than the atmospheric moisture transport and clearly overcompensated the effects of enhanced poleward heat transport in the North Atlantic, also resulting from the final closing of CAS. Once a major Greenland ice sheet was established near 3.18–3.12 Ma and, in particular, after 2.9 Ma, it together with the outlined secondary feedback mechanisms formed an ongoing nucleus for Quaternary-style climates and glaciations that persisted in the Northern Hemisphere over the last 2.8–3.0 My.

Conclusions

The transition from late Neogene to Early Quaternary environments at ~3.2–2.7 Ma was linked to the onset of major NHG, forming the most recent major event in the Earth's climate history. Among various hypotheses and models that tend to explain the complex forcing processes, the gradual constriction of the ITF may have helped precondition the climate system, in particular, at 3.2–3.0 Ma. The stepwise, in part shortly

reversible, final closure of the Central America seaways (CAS) at sill depths of less than 250–500 m forms the basis of the most important ‘Panama Hypothesis.’ This closure is now constrained to 3.2–2.7 Ma on the basis of the growing gradient in SSS between the southwest Caribbean and eastern equatorial Pacific. Each closing matched times of an increased discharge of IRD to the Greenland Sea. Models and North Atlantic sediment records likewise suggest that the closure induced a significant rise in poleward oceanic heat transport, in AMOC and drawdown of atmospheric CO₂ and, less significant, in the poleward flux of atmospheric moisture, a process counteracting the poleward heat flux with regard to NHG. The pronounced two-step intensification of the freshwater cap in the subarctic North Pacific formed the perhaps crucial twofold link between the closure of the CAS and NHG. (1) It lowered the atmospheric CO₂ level by impeding the outgassing of CO₂ from upwelled North Pacific deepwaters. (2) It led to a doubling of the low-saline Arctic throughflow that promoted the spread of perennial Arctic sea-ice and albedo and helped stabilize the cold EGC and Polar Front in the Nordic Seas after 3.1 Ma and, in particular, after 2.85 Ma. This current, in turn, formed a long-term climatic feedback mechanism and memory that fostered the growth of continental ice in Greenland and helped to bridge short-lasting reopenings of the CAS.

Since the time when [Penck and Brückner \(1901/1909\)](#) published their classic account of the Alpine Ice Ages, their division of the Pleistocene into four cold stages with intervening warm stages became a model that has been applied globally for numerous local stratigraphies. Today, it is considered that there have been, for example, some 30–40 glaciations of Scandinavia, but only a few were large enough to reach beyond the Baltic Sea, and most of these large ones occurred during the last ca. 1 Ma.

The onset of the recent Ice Age dates back much further than the Quaternary. An overall, long-term trend of cooling global climates occurred throughout the Tertiary. Although there were local precursors, significant glaciation began in eastern Antarctica in the late Oligocene (ca. 34 Ma). It was followed by glaciation in mountain areas through the Miocene, for example, in Alaska and Iceland. In most cases, the traces of early glaciations are restricted to individual sites. Knowledge of the extent of the glaciers or ice sheets is rather limited, although there are a few exceptions. They include the Great Patagonian Glaciation in southern South America and the early glaciations in the Nebraska–Iowa area of the United States, in Alaska, and in northwestern Canada, where the ancient ice sheets reached beyond the limits of all later glaciations.

Antarctica

The nature and timing of the initial glaciation of Antarctica is not well known, and the evolution and nature of the West Antarctic Ice Sheet (WAIS) remains controversial ([Wilson, 1995](#)). The Antarctic Ice Sheet has existed for about 35–40 My, since the mid-Tertiary, and it is widely believed that in East Antarctica, it reached continental proportions by the latest Eocene–early Oligocene ([Ingólfsson, 2004](#)). Existing reconstructions of pre-Quaternary Antarctic ice volumes and ice extent rely heavily on the interpretation of Ocean Drilling Program (ODP) data from offshore cores, such as oxygen isotope ($\delta^{18}\text{O}$) concentrations, ice-rafted detritus (IRD) concentrations, sediment type and clay mineralogy, microfossil assemblages, and occurrences of hiatuses. The available data indicate that the Antarctic glacial system has evolved through time: during early periods (Oligocene–Miocene), it was largely temperate in the coastal areas. A transition to cooler conditions followed in Pliocene, and during much of the Quaternary, it has been a stable, cold system.

South America

Neogene glaciation is known from the Piedmont areas of Argentina and Chile, where, like Antarctica, substantial ice

caps were established before 14 Ma. The earliest references concerning the Patagonian Glaciation had already been made by [Darwin \(1842\)](#), who identified erratic boulders in the Magellan Straits region. Widespread lowland glaciation began between 2.05 and 1.86 Ma, followed by the so-called ‘Initioglacial’ or ‘Great Patagonian Glaciation’ that took place 1.15–1.00 Ma. As [Coronato et al. \(2004\)](#) point out, it is considered that valley and piedmont glaciers flowed from the mountain ice sheet at the Andean summit several hundred kilometers eastward, in the Extra-Andean plains domain. Several times during the early Pleistocene, they probably reached the present Atlantic submarine platforms. The ice sheets reached a size comparable to the Late Weichselian Scandinavian Ice Sheet.

The recognition of the maximum extent of the different glacial advances is still largely based on the outstanding work of the Swedish geologist [Caldenius, published in 1932](#), after 3 years of intensive field work in Patagonia, covering an area of roughly one million square kilometers. Later authors have provided new evidence in support of Caldenius’ basic model, modifying his original schemes. Although the currently identified boundaries of the different glacial advances are highly coincident with those mapped by Caldenius, the total number of glaciations and their chronological correlation have changed. Morphologically, six or seven terminal ice positions of different absolute or relative ages can be distinguished.

The early glaciation of South America was not limited to Patagonia, although it is best documented there. But some glacial deposits, for example, in the Bolivian Andes, have been dated back to 3.27 My, and in Columbia, 2.5-My-old glacial meltwater deposits have been reported from the Bogotá basin.

Australasia

New Zealand’s earliest glaciation – the Ross Glaciation – is recognized from till and glacial lake beds interbedded with folded late Pliocene gravels in north Westland ([Gage, 1945](#)). The ice limits are unknown. The age of this glaciation is thought to be 2.4–2.5 Ma. The Porika Glaciation is probably younger, according to glacial deposits that rest on basement rocks and Pliocene gravel. Following these glaciations, a gap of at least a million years in the glacial history probably resulted from the dominance of uplift and erosion, with the present drainage pattern becoming progressively established. In New Zealand, glaciation – and especially evidence of early glaciation – is largely restricted to the South Island.

Traces of glaciation in Tasmania are limited to the last million years. The oldest event, the Linda Glaciation, was first identified in the Linda valley. Unfortunately, age control is poor. The early glacial deposits contain strongly weathered clasts, and paleomagnetic investigations of related meltwater deposits suggest that they are older than the Brunhes/Matuyama magnetic reversal boundary.

Africa

Even in Africa, with its traces of Quaternary glaciation being limited to very few high mountains, there is evidence of early Pleistocene glaciation. Traces of two old glaciations have been found on Mount Kilimanjaro, the oldest of which has been dated to about 2.0 Ma (Osmaston, 2004).

North America

In North America, the longest sequences are found in Alaska and the adjacent Northwest Territories of Canada, which together with the Rockies preserve evidence of glaciation from the Neogene to the present. In Montana, for instance, three tills have been identified dating back to early Pleistocene Marine Isotope Stages (MIS) 96, 82, and 78 (Fullerton et al., 2004).

During the Matuyama Chron (ca. 2.6 Ma), ice appears to have been largely absent from large areas of the southern prairie provinces in Canada and the adjacent states of Montana and North Dakota, as well as from the Arctic Islands. However, in Late Matuyama time (ca. 1.0 Ma), a modest Keewatin ice center formed, delivering ice as far distant as Banks Island, NWT. In contrast, from the Labrador/Hudson Bay glaciation center, ice spread as far south as Topeka in Kansas during both the Early and Late Matuyama (Roy et al., 2003). Traces of Early Matuyama Chron (ca. 2.0 Ma) glaciation are found in easternmost South Dakota, Minnesota, and Wisconsin. Late Matuyama Chron (ca. 1.0 Ma) glaciation seems to have extended eastward into Illinois, Indiana, Ohio, and Pennsylvania. Ice caps appear for the most part to have been far more extensive during the Brunhes Chron (ca. 0.5–0.6 Ma) than in the Matuyama, and only in the southern Midwestern states did Brunhes-age ice not reach previous limits (Barendregt and Duk-Rodkin, 2004). Consequently, the most investigated sites are restricted to those areas.

Glaciation of Greenland seems to have started some 14 Ma in the mountains, with contiguous ice sheets established from the earliest Pleistocene (ca. 2.6 Ma). The surprisingly short and incomplete glacial record from Greenland reflects the fact that the ice sheet appears to have extended to the shelf break during each of the glacial maxima. The most complete records are therefore probably found on the adjacent continental slope.

Europe

The Scandinavian Ice Sheet

The impressive erosional landforms of Norway, such as fjords and valleys, have been formed during multiple glaciations

(Mangerud et al., 1996). Unfortunately, these features cannot be dated. The oldest dated trace of glaciation is ice-rafted detritus (IRD) dropped from icebergs into the deep sea beyond the coast. IRD pulses are found from 12.6 Ma in cores from the Vøring Plateau outside the Norwegian coast (Fronval and Jansen, 1996), suggesting that the Scandinavian Ice Sheet first reached sea level at that time. A synthesis of observations of IRD in cores from the Nordic seas (Kleiven et al., 2002) indicates that there have been marked expansions of the Greenland Ice Sheet 3.3 Ma and of the Scandinavian Ice Sheet from 2.75 Ma. A series of prograding wedges, named the Naust Formation, is the youngest formation on the Mid-Norwegian continental shelf in the area between 64 and 68° N, that is, north of the North Sea Fan. The age of the base is considered to be ca. 2.8 Ma (Ottesen et al., 2009), that is, close to the recorded major increase in IRD in the Norwegian Sea. The formation is more than a kilometer thick over a large area, and the shelf edge prograded up to 150 km during the accumulation of this formation (Dahlgren et al., 2005; Ottesen et al., 2009; Rise et al., 2005). Scientists agree that the Naust Formation reflects a number of glaciations that covered a large part of mainland Norway; some consider that the entire formation was deposited during ice sheet advances to the paleo-shelf edge, whereas others consider that the older part reflects smaller mountain-centered ice sheets and that the ice margin reached the shelf edge for the first time about 1.1 Ma. The latter interpretation is partly based on the fact that the Fedje Till, the oldest dated till on the Norwegian shelf, is assigned an age of about 1.1 Ma (=MIS 34–36; Sejrup et al., 2005).

Also, in the Barents Sea region, initial glacial growth is reflected in a pronounced increase in the general sedimentation rate along the Svalbard margin from around 2.3 to 2.5 Ma. The volume of thick wedges of glaciogenic sediments along the western continental slope suggests that there has been as much as 1000–1500 m of erosion over the Barents Sea region since the onset of glaciation. Consequently, during the oldest glaciations, the physiography of the Barents Sea region must have been very different from the present and the shelf area was probably above sea level (Elverhøi et al., 1998; Vorren et al., 1998).

Sedimentological data from the ODP site 986 drilled off western Svalbard reveal low IRD values during the interval 2.3–1.6 Ma, suggesting that glaciers in the Barents Sea region did not reach the sea (Butt et al., 2000). However, further extensive glaciation seems to have begun around 1.5–1.3 Ma, and after 1.3 Ma, ice sheets expanded to the shelf break several times. The seismic stratigraphy suggests that the ice sheet in the southwestern Barents Sea expanded to the outer shelf at least eight times (Laberg and Vorren, 1996). The last period of glacial deposition appears to have been dominated by aggradation of glacial sediments on the shelf margin rather than progradation. This may reflect a different style of glaciation as the shelf was glacially eroded and eventually became submerged. Accordingly, Solheim et al. (1998) suggest that the thick eroding ice sheets of the oldest glaciations were later replaced by thinner ice sheets with more rapidly flowing ice streams in the marginal areas.

Deposits of pre-Elsterian glaciations have only been sporadically reported from Denmark. At Harreskov (Jutland), Early middle Pleistocene interglacial deposits occur; they can

possibly be correlated with the Cromerian Complex Stage 'Interglacial II' (?MIS 19/17). Between these Harreskovian interglacial deposits and the underlying beds of Tertiary clay, glaciolacustrine, and glaciofluvial sediments, a clay-rich diamicton, interpreted as till, has been found. The age of this oldest record of glaciation in Denmark is unknown. It might date either from the Menapian Stage (?MIS 34–36) or, more likely, from an older part of the Cromerian Complex or Bavelian Complex stages (?MIS 22/20), when an ice sheet advanced southward from the Scandinavian mountains. There are other sites in Jutland where gravelly strata are found between the Tertiary deposits and the lowermost tills. They consist mainly of quartzite and quartzitic sandstone and also contain ventifacts. These strata might comprise residual till material dating from this pre-Elsterian glaciation (Houmark-Nielsen, 2004).

Further south, early glaciation appears to be represented only by ice-rafted clasts, outside the mountain or high-latitude regions (e.g., in the Netherlands, lowland Germany, northwestern France, and Britain). In the Late Tertiary, the sea withdrew from the Northwest European Basin and fluvial deposition prevailed. The deposits of the resulting 'Baltic River System' can be traced from the island of Sylt well into the Netherlands and beneath the North Sea. They contain lydites from the southern Central German uplands, as well as large blocks of sandstone, which must have been transported by drift ice from the eastern Baltic region. The Hattem Beds of the Menapian (MIS 34/36: ca. 1.2 Ma) are the oldest strata in the Netherlands and North Germany that carry major quantities of Scandinavian erratics from East Fennoscandian and central Swedish (Dalarna) source areas (Zandstra, 1983). They are exposed in the Ytterbeck-Uelsen push moraine in Niedersachsen (Lower Saxony). They are interpreted as evidence of the first major ice advance beyond the limits of the present Baltic basin (Ehlers, 1996). However, in the Netherlands, some Scandinavian rocks are also found in the Harderwijk Formation of Eburonian age, dating back to almost 1.8 Ma, and some consider that they were also transported by glaciers.

Iceland

In Iceland, the oldest tillites in the stratigraphic column indicate that mountain glaciation first occurred there in the Miocene, more than 7–6 Ma. The Icelandic sequence includes as many as 30 glacial horizons since then. There is evidence to suggest a progressive growth of glaciers during late Pliocene, and full-scale glacial–interglacial cyclicity, with a recurring growth of regional ice caps recorded since 2.6 Ma (Geirsdóttir and Eiríksson, 1994). The first full-scale glaciation of Iceland, with an ice sheet covering most of the island, dates back to 2.2–2.1 Ma. Glaciations occurred periodically through the Quaternary Period, but the record is fragmented by repeated destruction of stratigraphical evidence by subsequent glaciations. One of the key sections for the Pliocene–Pleistocene glacial and environmental development on Iceland is the Tjörnes sequence in northern Iceland. There, in a 600-m-thick sequence of interbedded lavas, tills, and marine and terrestrial sediments, at least 14 glaciations have been recorded since 2.5–2.0 Ma. This is probably the best

preserved terrestrial record anywhere for early and middle Pleistocene glaciations in the North Atlantic region (Figures 1 and 2).

Southern Europe

Early glaciation of the Alps is still poorly understood. Part of Penck and Brückner's (1901/1909) original Günz glacial deposits are known to be reverse magnetized. They must date therefore to the Matuyama Chron (i.e., pre-0.78 Ma). Early glaciations have also been reported from the French, Italian,

Figure 1 Synthetic maps, showing the extent of glaciations. (a) Late Matuyama Chron, Northern Hemisphere (ca. 1.0 My), (b) Late Matuyama Chron, Southern Hemisphere, (c) Middle Pleistocene glacial maximum, Northern Hemisphere, and (d) Middle Pleistocene glacial maximum, Southern Hemisphere. Maps are based on Ehlers and Gibbard (2004a,b,c).

Figure 1 (Continued)

and Swiss parts of the mountains. However, in many cases, as with the northern Alpine Donau and Biber Stage deposits, much of the evidence is based on sediments indirectly of glacial origin, and the number and extent of early Alpine glaciations remain unknown.

Northwest Europe

The first outline of the Quaternary stratigraphy was established by the end of the nineteenth century. At that time, the actual length of the Ice Age was still unknown. It was assumed that Northwest Europe, like the Alps, had been affected by three glaciations. The glaciations were named after rivers, in the catchment areas of which their deposits were well exposed. The names Elsterian, Saalian, and Weichselian for the Northwest European glaciations first appeared in 1911 on the 1:25 000 map sheets of the Prussian Geological Survey, and they gained general acceptance in the 1920s.

After it was discovered that the Alps had been glaciated (at least) four times instead of three, there have been many attempts to identify corresponding numbers of glaciations elsewhere. However, no convincing evidence was found in Britain, Ireland, or western central Europe. It was further to the east that traces of earlier glaciations were eventually identified.

Oldest Glaciations of Russia

Originally, it was assumed that the maximum glaciation on the East European Plain was the late middle Pleistocene Dnieper (Saalian) glaciation. Dnieper-age deposits overlie tills of an older glaciation, the Oka ice sheet, correlated to the Elsterian. However, in the 1970s, it was discovered that the till of the southernmost lobe of the middle Pleistocene glaciation in Central Russia, unlike that in the Ukraine, was overlain by Muchkap interglacial sediments bearing the fauna of the Tiraspol (Cromer) Complex and by four to five paleosols of interglacial character (Velichko et al., 2004). Accordingly, this so-called Don glaciation, presumably ca. 0.6-My old (postdating the Brunhes/Matuyama boundary), could no longer be correlated with the Saalian in Western Europe, the Dnieper glaciation in the Ukraine, or with the Samarovo glaciation of Siberia; it most probably relates to Marine Isotope Stage (MIS) 16 (Iosifova et al., 2006; Molodkov and Bolikhovskaya, 2006). The thick tripartite diamict sequence of the Don glaciation consists mostly of locally derived fine-grained materials with rare small clasts of Scandinavian origin. Pebbles of northeastern provenance and corresponding fabrics are more noticeable. This suggests limited influence of the Fennoscandian ice dispersal center and dominant ice flow from the Arctic (Velichko et al., 2011). In Poland, the maximum San 1 glaciation related to MIS 16 and Cromer glacial B, when the Scandinavian ice reached the Carpathians, left a till positioned below the Ferdinandovian interglacial formation (Lindner and Marks, 2008). A possible equivalent event has been suggested in Eastern England (Lee et al., 2004), but this is greatly disputed by local researchers.

Later on, traces of even older glaciations within the Brunhes Chron were identified buried deep within the boreholes of Moscow Region. The lowermost Likovo till contains no Scandinavian erratics. It is separated by the Akulovo interglacial strata, with 11% extinct floristic taxa from the more extensive Setun till containing 40–60% Scandinavian igneous rocks in the clast composition (Velichko et al., 2011). The fabric is mostly northwest–southeast whereas northeast–southwest fabrics dominate the Don till. The Setun and Likovo tills are correlated with the Cromerian Glacial A and MIS 18 (Iosifova et al., 2006). The same stratigraphic position is characteristic of the Nidanian till of Poland (Lindner and Marks, 2008).

Farther eastward, stratigraphic analogs of these ancient tills have not strictly been proven, although the maximum glaciation of the eastern Russian Plain has recently been mapped as Donian (Astakhov, 2004). In Siberia, a probable counterpart of the Don glacial sequence is the Mansi till, known from several deep boreholes of the Ob–Irtysh area (Volkova et al., 2002).

Elsterian Glaciation (Elsterian Stage)

The oldest glacial event that has been proved by the existence of tills throughout the North European glaciated area is the Elsterian glaciation. This glaciation reached as far south as the northern margin of the central German uplands. It was also the first time that ice sheets were extensive enough that Scandinavian and British ice sheets met at the center of the North Sea. As drainage toward the north was blocked, a large ice-dammed lake formed in the North Sea. Eventually, around 455 000 BP, the water breached the Weald–Artois threshold and started to drain southward toward the Gulf of Biscay. The Channel was formed at first only as a major river system, and in the course of the following warm and cold stages it gradually widened to its present size.

The history of the English Channel was difficult to reconstruct. The key was to be found south of the Channel, in the Bay of Biscay. Toucanne et al. (2009a,b) have studied the Deep Sea Core MD01-2448. This 28.8-m long core, drilled at 44°46,790 N, 11°16,470 S in a water depth of 3460 m on top of the Charcot Seamount, was ideally positioned to document the general course of the Pleistocene as well as the sedimentary influx from the Channel. The sedimentary sequence reaches back to MIS 35 – which means that it covers a period of 1.2 Ma. Comparison with the oxygen isotope curve from the LR04 stack (Lisiecki and Raymo, 2005) shows that the sedimentary sequence is complete, without any major gaps. Thus, it has been possible to determine an important correlation point between the terrestrial and the marine Quaternary stratigraphy. The Elsterian Stage is to be correlated with MIS 12.

The Elsterian glaciation was characterized by intensive glaciofluvial erosion. Deep subglacially formed channels of Elsterian age can be traced into the Northern Netherlands, beneath the southern North Sea, and into Eastern England. However, Elsterian till in the Netherlands seems to be restricted to a few thin layers. A major part of the Elsterian tills may have been eroded during subsequent cold stages, although continuous till sheets of this age occur north of the Weser River. In the southern parts of Niedersachsen and in Nordrhein-Westfalen, the Elsterian glaciation can in most cases only be inferred from Scandinavian erratics in contemporaneous river terrace deposits. As the thrust sequences of the end moraines west of the Weser River contain no Elsterian till, it is assumed that the ice advance did not extend beyond that area.

In Sachsen (Saxony) and Thüringen (Thuringia), where the Elsterian sediments were not overridden by the Saalian or any other ice sheet, an accurate reconstruction of the maximum extent of the Elsterian glaciation is possible. Here the southern limit of Nordic erratics, the so-called 'flint line,' is considered to represent the Elsterian ice sheet limit. It is found at an altitude of 300–480 m a.s.l., dipping toward the west. In the Saxonian-Thuringian area, especially in the vast lignite open-cast mines, two Elsterian tills have been found. These ice advances were apparently separated by only a short interstadial warm period, the Miltitz Interval. During this interval, the ice melted at least as far north as Mecklenburg, but no afforestation occurred (Eissmann, 1975).

The Elsterian tills of West Germany normally contain a relatively large proportion of western Scandinavian material. Rhomb porphyries and other indicator clasts from south Norwegian source areas are frequently found, together with flint conglomerate from the bottom of the Skagerrak. However, in no case do Norwegian rocks predominate; at best they make up a small percent of the (crystalline + sedimentary) indicator rock assemblage. Finds of rhomb porphyries related to the Anglian tills of Norfolk suggest a Norwegian glacial influence reaching beyond the North Sea and into Britain. Rhomb porphyries also occur far to the east, in Elsterian tills around Leipzig. This early Norwegian–West Swedish influence was later replaced by a North Swedish–Finnish ice stream. Consequently, in eastern Germany and Poland, the 'Baltic' facies of Elsterian till represents the normal lithofacies. This means that the tills tend to be rich in Paleozoic limestones and poor in flint.

In Denmark, Elsterian tills are known from exposures near Esbjerg, as well as from the Røgle cliff on Fyn. Borehole information suggests that a bipartite Elsterian till exists in Denmark. Again, an earlier ice advance from the north, characterized by rhomb porphyries from the Oslo area, seems to have been followed by a Baltic ice advance, which carried greater amounts of flint and Paleozoic limestones.

In Britain, the Anglian (Elsterian) tills are the first widespread unequivocal evidence of large-scale Pleistocene glaciation. The arrival of the Anglian ice sheet caused the burial of the Kesgrave Formation in all but the southernmost part of East Anglia. The Anglian ice sheet advanced into and overrode the contemporary valley of the River Thames in Hertfordshire and also advanced into its southern tributary valleys. Throughout the region, subglacial tunnel valleys were formed, radiating broadly in parallel with the ice movement. In northeastern

Norfolk, ice from both Scandinavia and the British glaciation centers interacted during the Anglian Stage. The ice sheet terminated in a large ice-dammed lake in the southern North Sea Basin. Although up to five different Anglian tills can be distinguished in parts of East Anglia, no evidence of a major intervening ice-free period has so far been discovered (Ehlers et al., 1991).

In eastern Poland, a counterpart of the Elsterian is represented by the postmaximum San 2 glaciation, which left surficial tills south of the Saalian ice limit (Lindner and Marks, 2008). However, farther eastward in Bielorrussia and central Russia, the contemporaneous tills of the Oka glaciation are overlain by tills of more extensive Dnieper and Moscow (Saalian) glaciations and therefore have never been described on the surface (Velichko et al., 2011).

In West Siberia, the thick tills of the two-stage Shaitan glaciation overlain by more extensive Saalian tills and local analogs of the Holsteinian have long been correlated with the double Elster glaciation (Volkova et al., 2002). The double Lebed till of the Yenisei valley buried well below sea level is also thought to be of Elsterian age, because it is overlain by fluvial and marine sediments of Tobol (Holsteinian) type. Its counterparts, as suggested by geologists, may form the ultimate drift limit in the east of the Central Siberian Uplands (Astakhov, 2004). This easternmost drift limit turns northward along the 114th meridian to get lost beyond the Arctic Circle because of the lack of data.

The North Sea Fan outside the mouth of the Norwegian Channel has been a depocenter of glacial sediments from southern Scandinavia, at least from MIS 12. Four pre-Weichselian glaciogenic debris-flow packages that were correlated with MIS 12, 10, 8, and 6, respectively, are identified in the fan (Hjelstuen et al., 2005; Nygård et al., 2005; Sejrup et al., 2005), indicating that the ice stream reached the mouth of the channel each time.

Along the coast of Norway, north of the Channel, there are till sheets in the continental shelf, showing that the ice sheet reached the shelf edge several times during the last 0.5 My. The tills cannot be directly dated or correlated with glaciations on the continent, but it is postulated that they were deposited during the Elsterian, Saalian, and other glaciations that expanded far south on the continent (Dahlgren et al., 2005; Hjelstuen et al., 2005; Ottesen et al., 2009; Rise et al., 2005).

Holsteinian Stage and Wacken/Dömnitz Substage (Saalian Stage)

Between the Elsterian and the Saalian glaciations, two or three interglacial events occurred, separated by intervening cold-climate intervals. During the Holsteinian, Northwest Europe experienced a major marine transgression, which was considerably more extensive than during the Eemian or the Holocene. In contrast to the Eemian, when the maximum sea-level highstand occurred only after the early part of the interglacial, the Holsteinian sea invaded parts of Jutland and North Germany by the end of the Elsterian. This early transgression may have been caused by strong isostatic depression by the Elsterian ice sheet. Besides glacio-isostatic adjustment, long-term crustal movements have to be taken into account. While in North

Germany the maximum of the Holsteinian transgression (uncorrected for later compaction) is situated at -13.5 m, the same level in East Anglia in the Nar Valley is located at $+23$ m, so a height difference of 36.5 m remains. Beyond the reaches of the Holsteinian sea, the interglacial is represented by fossil soils and lacustrine and organic strata. The Holsteinian was followed by a cold period in which permafrost developed in central Europe. This is referred to as the Fuhne cold substage (Saalian Stage).

The first evidence of an additional interglacial following the Holsteinian was discovered in the early 1960s, independently at Dömnitz (Mecklenburg-Vorpommern) and Wacken (Schleswig-Holstein), from where sequences with full forest development have been described. No marine transgression is known from this Wacken/Dömnitz Substage (Saalian Stage). The introduction of this new interglacial event was initially met with widespread skepticism. However, today it has been widely accepted that this Dömnitz Interglacial really exists (Litt et al., 2007). Recently, yet another interglacial, the Reinsdorf, has been introduced from the Schöningen site. Most importantly, in continuous sequences from boreholes in maar lakes in Massif Central in France, two warm interglacials are described between the Holsteinian and the Eemian, and these are correlated with the Reinsdorf and Dömnitz of Germany (Beaulieu et al., 2001).

The Holsteinian marine sediments with temperate fauna in Russia are tentatively described only in the Arctic, where they are known from boreholes penetrating below present sea level. They are thought to be synchronous with better-studied fluvial and lacustrine sequences of Likhvin (Holsteinian) type in European Russia (Velichko et al., 2004) and Tobol alluvial formation of West Siberia (Arkhipov et al., 1986). The Likhvin interglacial formation of European Russia contains the so-called *Brasenia* macroflora and pollen-reflecting

peculiar vegetation in which *Carpinus* coexisted with *Abies* and *Picea* with an admixture of exotic taxa of oceanic climate plants such as *Taxus*, *Ilex*, and *Pterocarya*. The Siberian Tobol formation contains forest fauna and shells of the central-asiatic freshwater mollusk *Corbicula tibetensis (fluminalis)*, shows normal magnetic polarity, and yields thermoluminescence dates in the range 260–390 ka BP. The Tobol alluvium, formed in a climate milder than the present, grades upward into glaciolacustrine facies of the subsequent Samarovo glaciation.

Saalian Glaciation (Saalian Stage)

Older Saalian Glaciation

The Saalian glaciation, like the Weichselian, began in North Germany, Denmark, and the Netherlands with a nonglacial cold phase of unknown, but probably rather long, duration. This was interrupted by several interstadials before the continental ice sheets invaded North Germany and the Netherlands.

The extent of what is called 'the Older Saalian' ice advance in Germany is shown in Figure 1. This maximum Saalian ice advance is correlated with the Odranian glaciation in Poland and the Dnieper glaciation in the Ukraine. In the west, it reached the Lower Rhine and left behind enormous pushed end moraines in the Netherlands (Koster, 2005) (Figures 2 and 3).

In the Netherlands, the Saalian glaciation (i.e., the 'Older Saalian glaciation') was originally subdivided into five different phases, all represented by push moraines, while only a single Saalian till sheet has ever been found. The Older Saalian till there occurs in a number of strikingly different lithofacies types. However, the lithologies involved do not represent deposits of different glaciations but a sequence of different ice masses within a single major ice advance.

Figure 1 Extent of the Saalian glacial maximum. Reproduced from Ehlers J, Gibbard PL, and Hughes PD (eds.) (2011) *Quaternary Glaciations – Extent and Chronology, Part IV – A Closer Look, Developments in Quaternary Science*, vol. 15. Amsterdam: Elsevier.

In Denmark, three Saalian ice advances are distinguished; one of them is thought to be older than the German 'Older Saalian.' The oldest of these deposited a sandy, quartz-rich till, the Trelde Næs till, which contains abundant Norwegian rocks and other stones characteristic of an ice advance from a northerly direction. It is assumed that the ice crossed the border into Schleswig-Holstein. A second ice advance from a northeasterly direction followed, which – after accumulating fine-grained, coarsening-upward meltwater sands – deposited another sandy, quartz-rich till. This Ashoved till is characterized by a central Swedish indicator association (Kinne diabase) and Jurassic rocks incorporated at the margin of the Kattegat (Katholm erratics). This ice advance is probably the equivalent of the North German Older Saalian ice advance (Houmark-Nielsen, 2007).

In Britain, glaciation during what is almost certainly this phase is similar in its extent to that during the later Weichselian (Devensian) glaciation. Deposits from this Wolstonian Stage glaciation occur in the southern English Midlands, south of Birmingham, and in Yorkshire, Lincolnshire, and the Fenland Basin. The extent of ice lobes in the North Sea basin is poorly

known, but it is highly probable that British and Continental ice were confluent for a period during this phase.

At the end of the Older Saalian, the ice possibly melted back beyond the southern Baltic Sea coast before the Middle Saalian tills were deposited in Denmark and North Germany. The ice-free intervals between the individual ice advances of the Saalian in North Germany and adjoining areas are characterized by a lack of organic deposits, although all three advances left behind kettle holes that would have formed ideal sediment traps for the preservation of such deposits. Only during the subsequent Eemian Stage interglacial were those depressions foci of peat growth and gyttja, diatomite, or lake marl deposition. This seems to suggest that the ice-free periods were too short and/or too cold to allow extensive vegetational development.

Some striking intra-Saalian bleached loams on the Isle of Sylt (Figure 4) were most probably formed during an interstadial. The deep-penetrating wet bleach down to more than 10 m suggests pedogenesis under very moist conditions without permafrost. The pollen content of the bleached loam yielded evidence of open vegetation with grasses, *Calluna*, and other heathers (Ericaceae).

In Russia, for several decades, the Saalian was described as consisting of two substages: the maximum Dnieper correlated with Drenthe and the younger Moscow (or Warthe) glaciation separated by the Odintsovo (Roslavl) interglacial, presumably of MIS 7 interval. The age difference was supported by the difference in topography: only the area of the Moscow glaciation features spectacular push moraines and hummocky landscapes with boggy depressions containing Mikulino (Eemian) sediments. But now it is demonstrated beyond any doubt that the Roslavl strata with two deciduous pollen optima bear the Cromer fauna and flora and therefore the underlying till must be older than MIS 8 (Velichko et al., 2004).

Both Dnieper and Moscow glaciogenic sequences sandwiched between Likhvin (Holsteinian) and Mikulino (Eemian) interglaciations are currently related to MIS 6. The preceding Pechora (or Vologda) glaciation of northeastern provenance

Figure 2 Exposure in Saalian push moraine in The Netherlands.

Figure 3 Saalian push moraines in the Lower Rhine area of Germany and The Netherlands.

Figure 4 Drenthe till with Saalian interstadial paleosol on Sylt, Germany.

was less extensive and did not reach the Moscow region. Formerly, this so-called ‘Novaya Zemlya till’ was correlated with the Dnieper till. Such correlation is now impossible because in the northeastern Russian Plain, thick peats with U/Th dates ca. 200–250 and OSL dates 170–200 ka BP are found between the Moscow and Pechora tills (Astakhov, 2004). This allows correlation of the Pechora till with tills of MIS 8 but not with any tills of MIS 6 time.

The Samarov glacial maximum of West Siberia is still considered part of the Saalian glaciation. This age is determined from apparently confirmable contact between the Samarov glaciolacustrine strata and the underlying Tobol (Holsteinian) interglacial alluvium. Only one horizon of interglacial soils and peats overlying the Samarov till has been described. Beneath this till, two pre-Holsteinian tills can be distinguished in the sedimentary sequences filling buried valleys, overdeepened to 200–300 b.s.l. These old tills have been found very close to the Samarov glacial limit, but not beyond it. However, considering the scarcity of geological information from this region, a pre-Holsteinian glaciation may well have been the most extensive in eastern Central Siberia.

A similar problem to that in Europe is encountered in Siberia, where the less extensive Taz till is thought to represent MIS 6, whereas the maximum Samarov glaciation, traditionally correlated with the Dnieper glaciation in Europe and Drenthe, is related to MIS 8. This correlation was apparently supported by rather conspicuous glacial topography of the Taz glaciation area in places covered by late Pleistocene interglacial sediments. Lately, however, one of the interglacial marine formations, previously correlated with the Eemian, has been proven to underlie the Taz till of MIS 6 on the Lower Ob river (Astakhov and Nazarov, 2010). This apparently confirms that the maximum Samarov glaciation cannot be younger than MIS 8.

Immediately west of the Urals, the Saalian ice limits are also uncertain. The Saalian limit was most probably positioned in the Volga–Pechora interfluvial area, just north of the maximum drift limit.

Middle Saalian Glaciation

The subsequent ice advance began in North Germany with the deposition of meltwater sands. In contrast to the glaciofluvial

deposits of the Elsterian, which in North Germany are largely concentrated in buried channels, the meltwater of the Middle Saalian accumulated vast outwash fans, the deposits of which can be several tens of meters thick. During the maximum phase of this advance, when the ice lay south of the present Elbe valley, the meltwater drained southward and then, via the Aller–Weser ice-marginal valley (‘urstromtal’), toward the North Sea. It is thought that the Middle Saalian ice advanced at least as far west as the Altenwalder Geest hills, south of Cuxhaven. Within the area covered by the Middle Saalian glaciation, a number of marked end moraine ridges are found. They include the hills of the Neuenkirchen and Falkenberg ice-marginal positions.

In Denmark, the Trelde Næs till and Ashoved till (both Older Saalian) are overlain by a widespread chalk-rich Saalian till (Lillebælt till), separated from the older tills by sands. It is found from the German border to Northern Jutland in the north (Skærumhede). Lithologically, it resembles the North German Middle Saalian till. However, as this is the uppermost Saalian till in Denmark, the Lillebælt till has been correlated with the North German Younger Saalian till. It probably represents both tills.

Younger Saalian Glaciation

After the Middle Saalian glaciation, the ice margin retreated far to the northeast and parts of the ice sheet stagnated and melted *in situ*. The active ice margin probably lay in the present Baltic Sea area. In the proglacial zone, widespread dead ice masses were covered by outwash during the subsequent readvance.

Indicator counts have demonstrated that the composition of the Younger Saalian till varies locally. In northeastern Niedersachsen, a red-brown, east Baltic facies of the Younger Saalian till is widespread. At the outermost ice margin in Schleswig–Holstein, tills that are rich in east Baltic indicator clasts (e.g., at Hohenwestedt and Osterrade) have also been found. In immediately adjoining areas, however, the east Baltic components are lacking. For example, in northwestern Schleswig–Holstein, the flint content of this till is higher, so it cannot be distinguished from the Middle Saalian till.

A line of marked end moraines in the northern Lüneburger Heide area has traditionally been associated with the Younger Saalian ‘Warthe’ ice advance. However, more recent investigations show that many assumed Younger Saalian end moraines in Niedersachsen often have a much older core.

In contrast to the Middle Saalian glaciation, outwash accumulation during the Younger Saalian seems to have been rather limited. Many areas that were previously interpreted as Younger Saalian sandur plains have been found to be covered by patches of Middle Saalian till.

The Middle Saalian and Younger Saalian glaciations seem to be closely related. They are both probably the equivalents of Woldstedt’s Warthe (Warta) Substage (Figure 5). Further to the east, the Moscow glaciogenic sequence, the equivalent of the Polish Warta glaciation, makes vast hummocky terrains with large push moraines in Bielorrussia and Central Russia. The end moraines are fringed by huge boggy sandurs locally called ‘polesye.’ Toward the east, its outer limit converges with that of the Older Saalian (Dnieper) glaciation, and it may even have advanced beyond the Dnieper glacial limit. In West

Figure 5 Extent of the Saalian Moscow glaciation. Reproduced from Ehlers J, Gibbard PL, and Hughes PD (eds.) (2011) *Quaternary Glaciations – Extent and Chronology, Part IV – A Closer Look. Developments in Quaternary Science*, vol. 15. Amsterdam: Elsevier.

Siberia, the Taz (or Yenisei) glaciation, traditionally correlated with the Moscow–Warta Substage, is supposed to be the final middle Pleistocene event, ca. 140–170 ka BP according to luminescence dating.

Whereas the Saalian tills of Central Russia are undoubtedly Scandinavian, east of 54° E, both Saalian glaciations were centered on the Kara Sea shelf as seen from the fabrics and orientation of push moraines. The ice sheets were up to 1-km thick even close to the ice limit, which is indicated by foreign tills, erratics, and striations on flat summits of the Urals and Central Siberian Uplands. The maximum calculated ice thickness in the lowland Yamal Peninsula is 3.5 km. This Antarctic thickness is amply manifested in pervading overthrusts and other disharmonic disturbances of the Cretaceous and Cenozoic substrates, in places penetrating 300–400 m beneath the surface. The ice sheets operated mostly on the perennially frozen substrate. This is evident from many intraclasts of stratified sand that could be transported only in a frozen state and which constitute a sizeable volume of lowland tills poor in crystalline pebbles.

Other signatures of cold-based glaciation are the lack of flutes, eskers, and ice retreat features. Siberian tills are expressed in hummocky terrains, mostly over hard Palaeozoic rocks, whereas in sedimentary lowlands, they are overlain by sand in the form of outwash plains or ice-disintegration features such as kames (Astakhov, 2004). Shallow proglacial lakes left varves, mostly in the ice-dammed river valleys. The thickest glaciolacustrine silty rhythmites occur mainly beyond the Arctic Circle, where they often laterally grade into meltout diamictons. This was probably the deepest isostatic trough where stagnant remnants of disintegrated Saalian ice slowly decayed awaiting the Eemian transgression.

In the east of the Russian Arctic, stagnant middle Pleistocene glaciers have survived until our day because the subsequent

interglacial sea had negative temperatures. Continuous strata of deformed basal glacial ice, which are glacial deposits *sensu stricto*, led to the sensational reconstruction of an ice sheet of the final middle Pleistocene on the shelf and islands of the East Siberian Sea. The ice sheet of a rather modest extent, ~600 × 400 km, was located between longitudes 141 and 159° E, that is, in the far eastern area previously thought unfavorable for ice accumulation (Anisimov et al., 2006; Basilyan et al., 2008). Its main signature is not till but dirty glacier ice buried under frozen marine clay with a distinct thaw contact (Figure 6). Prior to this discovery, fossil glacier ice in Russia was known only as a remnant of the late Pleistocene glaciers.

As mentioned earlier, there are tills of assumed Saalian age on most of the Norwegian continental shelf, but the tills cannot be correlated precisely with the different tills in Germany. Dowdeswell et al. (2006) identified an ice-stream path from the Saalian that had a different direction and also was longer than the corresponding ice stream during the Late Weichselian.

The Alpine Glaciations

In the Alps, a marked asymmetry is observed between the glaciation of the northern and southern slopes. On the southern side of the Alps, the ELA is about 200 m higher than in the north. This contrast is further enhanced by the different altitudes of the two Alpine forelands (about 500 m in the north as opposed to about 100 m in the south). As a consequence, Quaternary glaciers advanced far into the northern foreland of the Alps, whereas in Italy they halted as soon as they reached the foot of the mountains.

The ice streams of the Alps have reshaped a preexisting fluvial relief to a glacially molded landscape. One characteristic element of this relief is the U-shaped valley troughs. The upper

Figure 6 Easternmost fossil ice preserved from the middle Pleistocene on the New Siberian Islands. (a) Middle Pleistocene basal glacier ice (MGI-1) overlain by marine clay and by late Pleistocene fossil glacier (MGI-2). (b) Middle Pleistocene fossil glacier (g) overlain by marine clay (m) with distinct thaw contact. Photographs by V. Tumskoy and A. Basilyan.

limit of glacial erosion ('Schliffgrenze') is well developed, especially in the central Alps. Since glacial erosion was much stronger in the main valleys than in the tributaries, many of the latter today finish as hanging valleys, high above the modern main valley floor.

Glacial erosion largely modified the original longitudinal profile (thalweg) of the valleys. Numerous overdeepened basins were formed. Seismic investigations in the Inn valley have revealed that Quaternary sediments reach a thickness of about 900–1000 m there. Between Wattens and Schafteuau, the base of the Quaternary lies at a depth of 300–400 m b.s.l. Overdeepened rock basins are found, especially in narrow sections of the Alpine valleys, where the ice had to pass at particularly high velocities. Where valley glaciers merged, pronounced excavation resulted in the formation of confluence basins (e.g., near Innertkirchen in the Aare Valley). The most noteworthy overdeepenings still visible in the field, however, are found near the outer margins of the glaciations. Glacial tongue basins occupied by deep lakes are characteristic of both the southern and northern Alpine margins (e.g., Lake Constance and Lake Garda). Overdeepening of the lake basins at the southern Alpine margin reaches maximum values of 660 m at Lago di Como and 680 m at Lago Maggiore, with Lago di Como being 410 m and Lago Maggiore 372 m deep at present.

The classic Alpine Quaternary sequence is largely a morphostratigraphy (Jerz, 1993). It is based upon the concept that the so-called glacial series formed during any ice advance consists of a sequence of tongue basins with drumlins, moraine belts, and gravel spreads. In the northern foothills of the Alps, comprehensive morphological sequences of this type were initially found for only three glaciations; for the fourth, this evidence was produced much later through investigations in Upper Austria. From the early Pleistocene, the Biber and Donau glaciations, no such landform assemblages have been preserved.

Penck and Brückner (1901/1909) did not consider any glacial deposits to be older than the Günz cold stage. Therefore, all gravel occurrences at higher altitudes than the

Mindel Stage 'Jüngere Deckenschotter' were summarily referred to as 'Ältere Deckenschotter' and assigned to the Günz cold stage. Today, the 'Ältere Deckenschotter' sensu stricto are distinguished from the older gravel spreads of the Donau and Biber cold stages.

Originally, it had been assumed that the Günz was younger than the Matuyama/Brunhes boundary. However, on the Höchsten and near Heiligenberg (north of Lake Constance), tills and gravels of the Günz glaciation were found to be reversely magnetized. Consequently, at least part of the Günz Complex has to be assigned to the Matuyama Epoch. Near Rosshaupten in the Allgäu, the Matuyama/Brunhes reversal has also been found above the 'Ältere Deckenschotter' of the Günz.

According to the latest investigations, the Günz comprises the deposits of three cold stages. The older parts of this Günz Complex are reversely magnetized. The majority of the deposits, however, seem to be younger than the Brunhes/Matuyama boundary. End moraines of Günz age have been identified only in the area between Iller and Wartach glacier tongues. Apparently, the Günz glaciers advanced further into the foreland in this region than anywhere else (Habbe, 2007).

While the relative stratigraphy of the gravel terraces is undisputed, the chronostratigraphical determination of the various early cold stages remains very problematic. First attempts to date the older gravels by means of cosmogenic nuclides have yielded an age of 2.35 Ma for the Günz gravels, south of Memmingen, and for the Mindel gravels, an age of 680 000 years (Häuselmann et al., 2007).

The exact number of glaciations in the Alps prior to the Riss Stage is uncertain. Between the Günz and the Mindel, a separate Haslach glaciation has been postulated, based on the occurrence of distinct gravel units in the Württemberg Rottal (south of Ulm). Today, the Haslach glaciation is largely accepted as an independent unit.

The 'Jüngere Deckenschotter' of the Mindel valley and their association with moraines north of Obergünzburg caused Penck to name his second Alpine glaciation the Mindel cold stage.

The interglacial between the Mindel and Riss cold stages in the Alps was traditionally referred to as the 'Great Interglacial.' It is correlated with the Holsteinian interglacial of Northern Germany. The interglacial is characterized by the presence of *Pterocarya* (winged nut), *Fagus* (beech), and *Buxus* (yew). There are two well-studied sites that fit these characteristics, namely, Borehole Samerberg 2 (Grüger, 1983) and the Thalgut site in Switzerland (Welten, 1988).

When the glaciers advanced again after the Mindel–Riss Interglacial, they encountered a landscape that had already been sculpted by earlier ice advances. At the alpine margin, tongue basins already existed. But in the Riss Stage, the glaciers in many areas advanced well beyond the maximum extent of the previous glaciations. The maximum glaciation in the Emmental region (Switzerland) and the correlative Höhenschotter gravels based on U/Th datings are now correlated with the MIS 6 (Riss) (Preusser, 2010).

In southern Germany, theories of what should be referred to as the 'Riss cold stage' have also undergone a marked change in the course of time. When they originally established their Alpine Quaternary chronology, Penck and Brückner started from the assumption that each of their four cold stages

represented a single, uniform glaciation. However, within the Rhine Glacier region, the Riss glaciation can be subdivided into three ice advances. The Older Riss deposits are marked by a greater degree of weathering; in the Riss valley and neighboring valleys, they underlie the deposits of the Middle Riss from which they are separated by gravels. The extent of the intervening glacial retreat has not yet been assessed. The differences in weathering give reason to believe that the break might have been at least of interstadial status. The distribution of the till of this first ice advance is restricted to former glacier tongues; accordingly, the Middle Riss is referred to as the Zungen-Riss ('tongue Riss').

In the eastern part of the Rhine Glacier region (between Biberach and Leutkirch), the Middle Riss is confined by a double rampart of end moraines, the so-called Doppelwall-Riss ('double rampart Riss'). The end moraines are generally gravelly push moraines 10–30 m in height, formed at an interval of 1–3 km. They delineate the margin of the Middle Riss glaciation in the eastern region of the Rhine Glacier. In contrast to this pronounced landform assemblage, the end moraine of the Younger Riss is incompletely developed. It includes the moraine ridges north of Ingoldingen and south of Eberhardzell, at the eastern margin of the former Rhine Glacier.

The stratigraphy of the Alpine Riss cold stage is still far from solved – at least in major parts of the glaciated area. Neither the precise extent of the glaciers nor the number of ice advances, or their age, can be determined with certainty yet. Under these conditions, a direct correlation of the classic Riss or parts of it with the Saalian glaciation of Northern Europe is not yet possible.

Contrary to the fourfold stratigraphic framework developed for Pleistocene terrestrial glacial sediments in central North America (Wisconsinan, Illinoian, Kansan, and Nebraskan; [Flint, 1957](#)), the record of global ice volume contained in the oxygen isotope ($\delta^{18}\text{O}$) record of deep-sea sediments provides an elaborate and more complete history of glaciations ([Figure 1](#); [Hays et al., 1976](#); [Imbrie et al., 1984](#); [Mix et al., 1995](#); [Ruddiman et al., 1989](#)). The beginning of middle Pleistocene time has been set at the last major magnetic reversal, 780 thousand years ago (ka), the transition from Matuyama Reversed Chron to the Brunhes Normal Chron ([Renne et al., 1994](#); [Shackleton et al., 1990](#); [Spell and McDougall, 1992](#)). Middle and late Pleistocene glaciations therefore are entirely within the Brunhes Normal Chron. Soon after the Brunhes–Matuyama reversal, the global ice volume increased significantly beginning with Marine Isotope Stage (MIS) 16, based on the magnitude of the $\delta^{18}\text{O}$ isotopic excursion, which is related to the volume of water transferred from oceans to land and stored as ice. It was also at this time that the period between glacial maxima became longer, increasing from approximately 41 000 years during the early Pleistocene to 100 000 years during the Middle and late Pleistocene ([Imbrie et al., 1993](#); [Pisias and Moore, 1981](#); [Ruddiman et al., 1989](#)).

The volume of continental ice inferred for peak middle Pleistocene glaciations dictates that the global extent of glaciation during these times was similar to the extent in the most recent glacial cycle. Limited stratigraphic preservation and exposure on land, however, have affected the ability to confirm the character and extent of these interpreted glacial events by mapping alone, except in places where the records of older glaciations were more extensive than younger events. Statistical simulations that follow the simple rule of ‘obliterative overlap’ – that is, that glaciations more extensive than prior glaciations obliterate the record of less extensive, older glaciations – determine the probability of moraine survival. Only 3 out of 10 random-size glaciations would be preserved at the surface if these very simplified rules are followed ([Gibbons et al., 1984](#)). A natural corollary is that the oldest glaciation preserved is also the most areally extensive record at the surface and that progressively younger glaciations are progressively less extensive. If this statistical argument is applied to the geological record, the mappable remnants of glaciations would be expected to represent the larger isotopic excursions of the middle Pleistocene – that is, MIS 16, 12, and 6. The basis for the original fourfold chronology in the midcontinent may therefore simply be a result of the statistical likelihood of moraine, till, and erratic survival at the surface.

In regions such as the midcontinent of North America, where older glaciations extend beyond the Late Wisconsinan ice margin, they have been described, at least qualitatively, for more than a century. Of these, the Illinoian (MIS 6), the only

pre-Wisconsinan glaciation that retains its original name, is the best documented ([Aber, 1999](#); [Hallberg, 1980a](#); [Williman and Frye, 1970](#)). The MIS 6 Lake Michigan lobe reached farther south than any other glaciation in southern Illinois ([Williman and Frye, 1970](#)), but farther west along the ice margin, the Illinoian ice was much less extensive than older glaciations. On the west side of the Driftless Area in Wisconsin, there are extensive areas of pre-Illinoian till at the surface; on the east side (e.g., in the Baraboo Hills of Wisconsin), the Late Wisconsinan MIS 2 ice reached as far as any older glaciation ([Farrand et al., 1984](#)). In the Rockies, there is variability in ice extent, with pre-MIS 6 (pre-Bull Lake) and/or MIS 6 (Bull Lake) till extending well beyond the MIS 2 (Pinedale) moraines in some areas (e.g., in the southwestern Wind River Range) but not detectable at all in other places ([Dahms, 2004](#); [Hall, 1999](#)).

While acknowledging the obvious limitation of the fragmentary nature of the terrestrial record of glaciations, correlation and dating of continental glacial records of possible middle Pleistocene age remains a priority to confirm, to the extent possible, the timing, extent, and character of the glacial cycles. Recent advances toward this goal have been due, in part, to progress in magnetostratigraphy and cosmogenic exposure and burial dating methods.

Correlation of Glaciated Landscapes

Where middle Pleistocene deposits outcrop, these landscapes have been separated from younger landscapes on the basis of soil development, depth of leaching, and degradation of glacial landforms (e.g., Cincinnati, Ohio; [Szabo and Chanda, 2004](#)). middle Pleistocene landscapes may also be eroded by wind and thereby display a faceted stone ‘lag’ or may be buried by loess or sand, especially where located near the Late Wisconsinan ice margin. These weathering and erosion horizons, where preserved, make the task of recognizing these older landscapes easier. However, these landscapes may have also been eroded by hillslope processes, especially those that allowed the movement of the active layer on low slopes when permafrost was present. This makes the task of recognizing them more difficult because of the removal of well-developed soils, as on the ‘Iowan Erosion Surface’ ([Ruhe, 1969](#)).

In mountain glacier systems, boulder weathering, pitting, grussification, and degradation of moraine form are commonly used as relative dating methods and have been supported by $^{36}\text{Cl}/^{10}\text{Be}$ exposure ages, for example, for the Bull Lake moraines in the Rockies, dated as being >130–95 ka ([Dahms, 2004](#)). In California, the Mono Basin glaciation was originally assigned to the middle Pleistocene based on these relative dating methods and has been confirmed as being MIS 6 based on ^{36}Cl exposure dates of 80–60 ka ([Gillespie and](#)

Figure 1 Geomagnetic polarity timescale for LR04 benthic and $\delta^{18}\text{O}$ paleotemperature profile. Black (white) areas represent normal (reversed) polarity. Marine Isotope Stages (MIS) are labeled on LR04 (even numbers represent glacials and odd numbers interglacials). MIS scheme follows Ruddiman et al. (1989) and Raymo et al. (1989) from the present to MIS 104 and Shackleton et al. (1995) in the Gauss Chron. Arrow marks Holocene mean $\delta^{18}\text{O}$. *Gradstein et al. (2004) and Pillans and Naish (2004). Reproduced from Lisiecki LE and Raymo ME (2005) A Pliocene–Pleistocene stack of 57 globally distributed benthic $\delta^{18}\text{O}$ records. *Paleoceanography* 20, with permission.

Zehfuss, 2004). Alaska has a particularly well-preserved middle Pleistocene record owing to the limited extent of Wisconsin ice. Glacial units were qualitatively dated by relative weathering, paleosol formation, and tectonic evolution and further bracketed in time by magnetic chronology of underlying sediment and overlying basalts and amino-acid racemization dates on underlying shells (Hamilton, 2001; Manley et al., 2001). There are exceptions, however, where surfaces that were assumed to belong to 'early' glaciations because of their relative weathering and discontinuous preservation are actually younger than expected. One such landscape, represented by scattered granitoid erratics southwest of the Missouri River in North Dakota, was tentatively revised as being early Late Wisconsin in age, between 27.8 and 28.8 ka, based on ^{36}Cl exposure dating (Manz, 2005). Similarly, on Baffin Island, young erratics indicated that heavily weathered upland surfaces had been overrun by latest Pleistocene ice that was cold based (Bierman et al., 1999; Marsella et al., 2000).

In the Midwest, particularly in Iowa and Missouri, the pre-Illinoian tills have good continuity in the subsurface and are distinct enough lithologically to correlate over broad areas (Hallberg, 1980a,b; Rovey and Kean, 1996). However, this is not the case everywhere with pre-Illinoian units at the surface. If the till sheets are discontinuous, it can be difficult to extend the exposed units into the subsurface, especially if tills of different age are lithologically similar and lack identifiable horizons. For example, pre-Illinoian deposits exposed in a limited area at the surface in New Jersey have not been correlated to subsurface units anywhere in New England (Stone et al., 2002). In some places, it is even difficult to distinguish Pleistocene units from remnants of pre-Pleistocene units in the subsurface (e.g., Nova Scotia; Stea, 2004).

In some areas, there are no older ice margins on land that extend beyond the Late Wisconsin margin (e.g., Maine; Borns et al., 2004) or they extend for only a short distance (e.g., Pennsylvania, Braun, 2004; Montana, Fullerton et al., 2004). Additionally, in many places outside the midwestern United States, subglacial erosion during the last glaciation has removed all but a few patches of glacial sediment attributed to glaciations prior to MIS 2 (e.g., New York, Cadwell and Muller, 2004; Nova Scotia, Stea, 2004). This appears to be more commonly reported in the east, where crystalline substrates produced sandy tills that are more easily reworked during subsequent glaciations.

In areas where thick glacial sequences are preserved (e.g., South Dakota, Minnesota, Michigan, Iowa, and Missouri), the till is derived from fine-grained sedimentary rocks (Soller, 2004) and is therefore more cohesive and resistant to erosion. However, the lack of subsurface information away from natural exposures even in the areas where thick sequences are preserved makes distinguishing the remnants of older glaciations very difficult. Most geological surveys have simply lumped similar glacial units or 'counted down from the top,' attributing units in the same stratigraphic position to the same glaciation. For example, in New Hampshire, units older than Wisconsin glaciation in the subsurface have traditionally been treated as a single older unit of Illinoian age (Koteff and Pessl, 1985). In Minnesota, tills in the subsurface that are presumed to be pre-Late Wisconsin have only recently been distinguished and correlated regionally, mainly on the

basis of details in texture and lithology rather than on dated horizons (Meyer, 1997, 2005). In exposures or cores, the distinctions are problematic if soil profiles are truncated or if the time between glaciations did not allow recognizable weathering profiles to develop.

Dating Tools

Dating tools that have been used to confirm or refute suggested middle Pleistocene ages include amino-acid racemization; optically stimulated luminescence of sediment formerly exposed to light (e.g., loess); uranium–thorium dating of shells where they are incorporated or of calcrete soils that cap glacial units; radionuclide dating of volcanic ashes or lava where they intercalate glacial deposits; magnetostratigraphy; and cosmogenic isotope dating. The latter two techniques rely less on fortunate occurrences of datable material and are being more widely applied.

Magnetostratigraphy can place normally magnetized sediment of the middle Pleistocene within the Brunhes Normal Chron (Barendregt and Duk-Rodkin, 2004) and is especially useful if transition from the Matuyama Reversed Chron is captured in a sequence because it marks a unique event in time. In Pennsylvania, large proglacial lakes record the transition from Matuyama to Brunhes (Braun, 2004). In Missouri, the early Pleistocene, reversed Moberly Formation is distinguished from three overlying normally magnetized middle Pleistocene units of the McCredie Formation (Colgan, 1999; Rovey and Kean, 1996). The same sequence is present in Iowa; the reversed Alburnett Formation is overlain by three normal tills of the Wolf Creek Formation (Baker and Stewart, 1984; Rovey et al., 2002). Findings from northeastern Kansas and northwestern Missouri (Aber, 1991) restricted the 'classical Kansas' till (now Independence Formation) to the age range ~600–700 ka based on the normal polarity of the till and a dated volcanic ash. The Independence Formation is therefore related to MIS 16 (or possibly 18), the most extensive glaciation with a record preserved on land in the central United States. Also for the midcontinent, Roy et al. (2004a,b) presented magnetostratigraphical data together with dated units that are constrained by three volcanic ashes (0.6, 1.2, and 2.0 Ma) derived from eruptions of the Yellowstone Caldera present in the sections (Boellstorff, 1978; Izett, 1981). They presented a summary map of the limit of Early and middle Pleistocene ice in eastern North America, in which a large fraction of the glacial deposits are now assigned to the middle Pleistocene (Figure 2; Roy et al., 2004a,b). The southernmost border of the eastern portion of the ice sheet extends from northeastern Kansas through Missouri, southern Illinois, the southern tip of Indiana, the northern part of Kentucky, includes all of Ohio, crosses the middle of West Virginia, and includes all of New York and the northern part of New Jersey.

A great deal of paleomagnetic work has been conducted in northwestern North America. An isolated and uncorrelated section in southwestern Saskatchewan includes till that is interpreted as being middle Pleistocene in age based on magnetic polarity. This interpretation is strengthened by the age of an underlying tephra and an underlying assemblage of mammal fossils (Barendregt et al., 1991). In Montana and Alberta,

Figure 2 Location of the stratigraphic sections investigated in relation to the maximum ice limit of late Cenozoic glaciations. Symbols correspond to the till stratigraphy exposed at each site: solid diamonds, late Pliocene R2 tills (~ 2.7 – 1.3 My); solid circles, middle Pleistocene N tills (~ 0.8 – 0.25 My); solid squares, late Pleistocene LGM tills (~ 17 ka). Age constraints are provided by three volcanic ashes and the Brunhes–Matuyama magnetic reversal. Current chronological methods do not allow the dating of individual ice advances, and each till group represents multiple ice advances. Open symbols correspond to till units with uncertain magnetic polarity but of lithological composition similar to their corresponding till group category. Volcanic ash localities: sites 4, 8, 9, and 10. Reproduced from Roy M, Clark PU, Raisbeck GM, and Yiou F (2004) Geochemical constraints on the regolith hypothesis for the Middle Pleistocene transition. *Earth and Planetary Science Letters* 227: 281–296, with permission.

paleomagnetism was used to decide between two age estimates for the Kennedy Drift, composed of tills and paleosols. The inferred rates of soil development placed the paleosols within the middle Pleistocene (younger than 800 ka) or in the Pliocene (>2600 ka). Paleomagnetism demonstrated the presence of six glacial and six interglacial episodes that span that time, beginning in the Gauss Normal Chron and continuing through

the Matuyama Reversed Chron and ending during the Brunhes Normal Chron (Cioppa et al., 1995). In the Pacific Northwest, a middle Pleistocene flood deposit is recognized by its normal polarity and capping calcrete soil with a 200 to >400 ka Th/U date, whereas earlier flood deposits in the sequence had a reversed polarity (Bjornstad et al., 2001). On Banks Island in the Canadian Arctic Archipelago, the strata exposed in the

Figure 3 Proposed distribution and timing of Brunhes/middle Pleistocene ice sheets in northwest North America. Montane glaciations for northern and northwestern Alaska are not included. Reproduced from Barendregt RW and Duk-Rodkin A (2004) Chronology and extent of Late Cenozoic ice sheets in North America: A magnetostratigraphic assessment. In Ehlers J and Gibbard PL (eds.) *Quaternary Glaciations – Extent and Chronology, Part II: North America*, pp. 1–7. Amsterdam: Elsevier.

Nelson River Bluffs and nearby outcrops span the Pleistocene. They record the Brunhes–Matuyama boundary within an interglacial deposit and preserve the deposits of an unnamed middle Pleistocene glaciation (<780 ka), unnamed interglacials (one

or more) between 780 and 130 ka, and the previously recognized middle Pleistocene (Illinoian) Thomsen glaciation (>130 ka). The latter is constrained by the inferred Sangamonian age of the capping paleosol (Barendregt et al., 1998).

A long sequence in the Mackenzie Mountains in the Northwest Territories begins in the late Tertiary (Gauss-normal); has two reversed tills (Matuyama) and, as its upper units, three normal tills (Brunhes); and is further constrained by means of ^{36}Cl dating of exposed boulders and multiple paleosols (Duk-Rodkin et al., 1996, 2004).

The collective results of the magnetostratigraphic work in the west have been interpreted to support a reconstruction of paleo-ice centers and the number of middle Pleistocene glaciations related to these proposed centers: Cordilleran Ice Sheet, three glaciations; the Horton Ice Cap/Keewatin Ice Sheet, three glaciations. These ice centers are proposed in areas near the late Pleistocene, Laurentide ice centers but the ice sheets were apparently less extensive (Figure 3; Barendregt and Duk-Rodkin, 2004; Barendregt and Irving, 1998).

Other refinements in the dating of middle Pleistocene glaciations have been the result of the application of cosmogenic exposure dating. Exposed, striated quartzite lying beyond the Late Wisconsinan glacial limit in southwestern Minnesota revealed a complex burial history that indicated the striations were between 640 and 740 ka (MIS 16; Bierman et al., 1999). Stratigraphic interpretations do not have this region affected by glaciation after this time. In some places, outcrops that have been glaciated during Wisconsinan time preserve an inherited cosmogenic nuclide abundance that is more a signature of limited Late Wisconsinan erosion, owing perhaps to cold-based glaciation, than the true exposure age of the rock (Baffin Island, Bierman et al., 1999; Wisconsin, Colgan et al., 2002; Puget Lowland, Washington, Briner and Swanson, 1998; and Arctic Canada, Briner et al., 2003).

The use of the disequilibrium of two radioactive, cosmogenic nuclides that have decayed since the burial of previously exposed sediment can constrain the age of that surface (Balco et al., 2005). In southwestern Minnesota and eastern South Dakota, the minimum limiting age for tills previously known only as pre-Wisconsinan was determined to be >500 ka (Balco et al., 2005b). A core in eastern Nebraska revealed that the Loveland Loess (135–150 ka) (Forman and Pierson, 2002) overlay an unnamed loess with a best-fit burial age of MIS 14–16. This loess overlaid the youngest till in eastern Nebraska (Balco et al., 2005a,b), most likely of MIS 16. In general, paleosols with long exposure periods produced the best burial ages, and this technique is therefore more effective in the southern tier of states, where the time between glaciations was longer (Balco et al., 2005c).

Middle Pleistocene Glaciations in the Southern Hemisphere

A Coronato and J Rabassa, Centro Austral de Investigaciones Científicas (CADIC-CONICET), Ushuaia, Argentina

© 2013 Elsevier B.V. All rights reserved.

Introduction

Middle Pleistocene glaciations are understood to be one of the consequences of climatic cooling forced by solar radiation variation during the 100-ka period cycles driven by Earth's orbit eccentricity.

The marine isotope stage (MIS) curves reflect high frequency and intensive periods of low $\delta^{18}\text{O}$ since 0.88 Ma (MIS 22) and throughout the subsequent Brunhes Normal magnetic polarity chron. According to Ehlers and Gibbard (2007), MIS 22 is the first of the colder events in which critical $\delta^{18}\text{O}$ values ($\sim 5.55\text{‰}$) were reached, which allowed continental ice cap formation in mid-latitudes, thus defining the critical conditions during the following middle Pleistocene times. This time spans the period between 780 ka, when the magnetic polarity changed from reverse to normal, and ~ 130 ka, when the last interglacial period began.

Although there are fewer land masses in the Southern Hemisphere in comparison to the Northern Hemisphere, evidence for the middle Pleistocene glaciations has been recognized, mostly through geomorphological mapping and cosmogenic exposure dating. The latter uses ^{10}Be , ^{26}Al , and ^{36}Cl , as well as ^{39}Ar – ^{40}Ar incremental heating techniques on basaltic rocks related to till units. The dates obtained have been correlated with the $\delta^{18}\text{O}$ MIS or with Antarctic temperature curves, depending on the author's decisions. This work shows how the cosmogenic and ^{39}Ar – ^{40}Ar dates presented herein correspond to the cold periods in the MIS curve produced by Lisiecki and Raymo (2005), in which the benthic $\delta^{18}\text{O}$ records of 57 globally distributed sites were averaged.

Knowledge of these glaciations has been improved by recent work in the Central Andes (Bolivia and Peru), as well as on the eastern slope of the Southern Andes (Patagonia, Argentina), in the New Zealand Alps, and in the western ranges of Tasmania. As this contribution is an updated review of Coronato and Rabassa (2007), only post-2005 findings and the literature not previously considered is presented herein. For previous work and other references, the reader should consult the authors' article in the first edition of the *Encyclopedia of Quaternary Science*.

South America

Intensive research has been performed during the last few years in the Central Andes in Bolivia and Peru, mainly on the basis of geomorphological surveying using digital terrain models (DTM), accompanied by satellite imagery and chronological studies using cosmogenic exposure dating techniques on moraine boulders.

Pre-Last Glacial Maximum (pre-LGM) moraines have been identified in the Cojup and Queshgue valleys in Cordillera

Blanca (9° – 10° S), Perú (Farber et al., 2005). Assuming that there has been no subsequent erosion of the boulder surfaces, ^{10}Be exposure ages of ~ 120 , 225, and 440 ka were obtained. These dates roughly correlate with MIS 4, the end of the MIS 8, and MIS 12 cooler periods in the ocean sequences (Figure 1), respectively. As a consequence of the poor constraint of the boulder surface erosion rate, the authors consider that these ages should be regarded as only tentative at this stage. Nevertheless, geomorphological relationships confirm that moraines carrying these boulders predate the LGM as well as the last interglacial period. Consequently, they could be considered as of middle Pleistocene age. Farber et al. (2005) suggested that maximum tropical alpine ice volume occurred during the middle Pleistocene at MIS 12 or later. The ice was considerably less extensive during the LGM.

In the Central Peruvian Andes, ^{10}Be and ^{26}Al cosmogenic radionuclide dating was undertaken in order to understand the pre-LGM glacial chronology. Here, Smith et al. (2005) obtained a set of dates from over a hundred boulders on moraines developed in valleys bordering the Junín Plains. The resulting chronology spans multiple glacial cycles, including boulder ages exceeding 1 Ma. This suggests that boulder erosion has been very low through this period. Two major groups of ages, within the set of no erosion/no uplift exposure ages on 10 dated moraines, were distinguished in the ranges ~ 440 – 325 and ~ 280 – 50 ka. Although it is not possible to establish clear morphological and chronological relationships, the data obtained suggest that middle Pleistocene glacial advances occurred repeatedly in the Junín Plain during MIS 12 at the end of MIS 10 and during MIS 6. This compares well with the global MIS (cf. Lisiecki and Raymo, 2005) sequence (Figure 1).

The history of middle and late Pleistocene regional glaciations has been interpreted from limnological studies in Lake Titicaca in the Bolivian Highlands (Altiplano). Lake-level variations were interpreted from magnetic susceptibility, total organic carbon (TOC), total inorganic carbon (TIC), calcium carbonate content, benthic and saline diatom assemblages, and $\delta^{13}\text{C}$ analyses, assuming that lake high-stands represent glaciations in the tropical Andes triggered by a combination of low temperatures and higher precipitation (Fritz et al., 2007). Thus, the lower part of the sequence was interpreted by these authors to indicate that regional glaciations could have expanded during 370–324, 300–238, 230–213, and 188–132 ka BP, perhaps during the colder events MIS 10, 8, and 6 (Figure 1). The proposed ages were obtained from an age model based on bulk organic carbon samples distributed into the acceptable confidence range (Hughen et al., 2004). The record of Lake Titicaca fresher and deeper conditions offer a middle Pleistocene paleoclimatic reference for geomorphological and cosmogenic studies in the glaciated valleys of the tropical Andes from which superficial absolute ages could potentially be controlled.

Figure 1 Middle Pleistocene glaciations recognized in the Central and Southern Andes, South America, New Zealand, and Tasmania, from the works cited in this article. The solid light blue lines indicate the absolute ages of moraines, mainly obtained by cosmogenic radionuclide determinations. The dashed light blue lines indicate the age of lava flows constraining the pre-Last Glacial Maximum sequence of six moraine belts. Lake Titicaca and ODPS 1119 provide sedimentary evidence of cold stages from core analyses, while the other localities give geomorphological glacial evidence. Core ODPS 1119 is located at 44° S–171° E, its paleoclimatic results derived from natural gamma-ray emission records that represent clay content variations corresponding to changes in the supply rate of glacial rock flour from the Pleistocene ice cap located immediately to the west, in the South Island of New Zealand (Carter and Gammon, 2004). CB, Cordillera Blanca (Peru); LT, Lago Titicaca (Bolivia); JP, Junín Plain (Peru); LBA, Lago Buenos Aires (Argentina); LP, Lago Pueyrredón (Argentina); PG, Poplar Gully in the Hope Valley (New Zealand); ODPS 1119, Ocean Drilling Project Site, in the NW Pacific Ocean; HV, Hesperus valley (Tasmania); P/N/HV, Pluto, Neptuno and Hayes valleys (Tasmania).

The glacial chronostratigraphy, formerly established for the Central Andes at latitude 36° in the Río Mendoza upper basin (eastern slope of the Andes, Argentina), has been recently rejected by Fauqué et al. (2009). Strong field and laboratory evidence supports a new interpretation for glacial deposits previously known as the Punta de Vacas, Penitentes, Horcones, Almacenes, and Confluencia drifts (cf. Coronato and Rabassa, 2007, for details). Most of these deposits were interpreted as mass-wasting deposits by Fauqué et al. (2009), who demonstrated that debris flow and mega-landslides, including true glacial boulders, occurred several times along the middle and late Pleistocene. These gravity flow deposits overlaid previous glacial deposits and reshaped them as mass-wasting accumulation landforms at the bottom of the Horcones and Cuevas valleys. Glacial deposits at 100–150 m above the valley bottom represent the middle Pleistocene Penitentes drift which was unaffected by the debris flow, but the lower glacial deposits along the main valleys would have thus been reworked. Fauqué et al. (2009) argued, on the basis of ^{36}Cl cosmogenic exposure dating and radiocarbon ages, that mass-wasting processes had a stronger impact on the landscape modeling than did the middle to late Pleistocene glaciers.

Comprehensive reviews of middle Pleistocene glaciations in Patagonia, between 39° S and 46° S are given by Glasser et al. (2008), Rabassa (2008), and Rabassa and Coronato (2009). In addition, Coronato and Rabassa (2011) and Martínez et al. (2011) have offered detailed information for most of the transverse glacial valleys of the Patagonian Andes.

The Lago Buenos Aires (46° 30' S) early to late Pleistocene glacial sequence (Kaplan et al., 2005) is so far the most

completely dated sequence. ^{10}Be , ^{26}Al , and ^{36}Cl exposure surface dating of morainic boulders as well as $^{40}\text{Ar}/^{39}\text{Ar}$ dating of basaltic rocks associated with till units or glacial landforms were applied. A detailed chronostratigraphy is still required for the six middle Pleistocene morainic belts recognized. The Moreno and Deseado moraines, deposited during ice expansion onto the Patagonian plains, were dated to between 760 and 200 ka. This means not only that they predate the LGM but also that they postdate the greatest Patagonian glaciation (GGP), the latter occurring at 1.1–1.0 Ma (cf. Coronato et al., 2004; Rabassa, 2008, for details). The maximum age of these moraines is given by $^{40}\text{Ar}/^{39}\text{Ar}$ dating of the Arroyo Page volcanic rocks, whereas their minimum age is given by cosmogenic exposure ages of boulders on the Moreno moraines. This broad period of time roughly correlates with the MIS 8–18 intervals. Between 150 and 140 ka, another expansion of glacial ice occurred forming the younger Moreno moraines, during MIS 6. As the moraines corresponding to MIS 4 have not yet been found, it was assumed by Kaplan et al. (2005) that they would have probably been overrun and removed by the ice during subsequent LGM times. Likewise, MIS 8 moraines (if they existed) may have been obliterated during the MIS 6 glacial advance.

The age of the last middle Pleistocene glaciations, proposed by Kaplan et al. (2005), was constrained by Phillips et al. (2006) using $^{230}\text{Th}/^{234}\text{U}$ analyses on soil carbonate formed in outwash gravel plains, correlated with the Moreno II terminal moraines. The results indicated that calcic pedogenesis began between 170 ± 8.3 and 146 ± 4.8 ka (MIS 6), with a subsequent period of pedogenesis constrained between

80.3 ± 1.8 and 38.9 ± 1.9 ka. This broadly corresponds to the MIS 4 cold period.

To the south, in the Lago Pueyrredón valley ($47^\circ 30' \text{ S}$), ^{10}Be cosmogenic surface exposure dating was performed on cobbles from old outwash terraces by Hein et al. (2009). Three pre-LGM moraine limits and related outwash plains were mapped by the authors and named, mostly following Caldenius (1932), from younger to older; the Hatcher, Caracoles, and Gorra de Poivre glaciations. On that basis and according to previous geomorphological and paleomagnetic studies, Hein et al. (2009) proposed a mean age of 260 ka (MIS 8) for the Hatcher glaciation. This interpretation does not correlate with its geomorphological equivalent glacial limit at Lago Buenos Aires where moraines in a similar topographic position with respect to the LGM limits were dated close to MIS 6 (Kaplan et al., 2005). In contrast to the Lago Buenos Aires sequence, glacial deposits related to cold events during MIS 6 and 4 were not found in the Lago Pueyrredón valley. This might result from erosion during the later LGM when the glaciers were confined to the valley at the same topographic position as during previous glaciations but lower than during the MIS 8 glaciation.

In view of the fact that the number of middle Pleistocene glacial limits currently identified in Patagonian valleys varies from two to three between the Great Patagonian Glaciation (GPG) and the LGM, as noted by Coronato et al. (2004), and in order to favor regional correlations, these middle Pleistocene events were referred to as post-GGP one to three glaciations.

Southern Pacific Ocean Islands

Based on detailed stratigraphy, depositional models, and optical dating chronology, pre-LGM glacial deposits have been identified in the Hope Valley (42° S) on the South Island of New Zealand (Rother et al., 2010). As these glaciations occurred in a maritime perhumid climate, where runoff erosion is exacerbated in the mountains, it is quite difficult to find deposits older than those belonging to the LGM and the MIS 5 interglacial period. Nevertheless, the Popplar Gully sedimentary sequence in the Hope Valley shows that the LGM glaciers extended down valley but nested into the main valleys, without eroding former upslope glacial deposits. Rother et al. (2010) demonstrated that the majority of the local valley infillings were not deposited during the LGM, but on the contrary, during MIS 5, 4, and 3 based on thermoluminescence (TL) dates of $95.7\text{--}32.1$ ka. These authors suggested that the deposits were laid down during periods of MIS 5–3 and the colder period MIS 4. Glacial sediments of MIS 6 or even earlier were deposited on the upper slopes of the Hope Valley and throughout the valley. They were overridden and reshaped during the last glacial advance. As the late middle Pleistocene glacial deposits identified are more voluminous than those of the LGM cycle, it is thought that the MIS 6 glaciers excavated larger and deeper valleys than during the younger glacial advances. Moreover, the aggradation surface during MIS 6 was calculated at least 120 m above the LGM surface.

New *in situ* cosmogenic ^{10}Be and ^{26}Al exposure ages were recently reported by Kiernan et al. (2010) from moraine boulders in the Tasmanian western ranges. Several of those

moraines were previously interpreted as of LGM in age. On the contrary, Kiernan et al. (2010) presented evidence that they were deposited during middle–late Pleistocene glaciations. They also confirmed that glaciers at that time were significantly larger than during the LGM. The MIS 6 glaciation was interpreted from the average ^{10}Be erosion-corrected cosmogenic exposure ages of 149 ± 14 and 127 ± 12 ka in the Hesperus glacier valley (Western Arthur range, 42° S). Similar ages were obtained in the nearby valley of Neptune glacier. The MIS 8–10 glaciations were interpreted as being represented by lateral and interlobate moraines developed in the Pluto and Neptuno–Hayes glacier valleys based upon ^{10}Be erosion-corrected cosmogenic exposure average ages of 220 ± 12 , 232 ± 13 , and 220 ± 12 ka. Figure 1 shows that the proposed ages for the Hesperus valley fully match those from the end of MIS 6, but the age of the interlobate moraines of Pluto and Neptuno/Hayes fall into the end of MIS 8, instead of MIS 10. They are very close to the beginning of the warm trend represented by MIS 7.

Although the association of moraine formation, based on boulder exposure ages, and MIS cold events is not completely definitive, the close match between boulder ages and the $\delta^{18}\text{O}$ scale suggests that glaciers advanced down to elevations of $\sim 750\text{--}320$ m a.s.l. in the western Tasmanian mountains. The ages and geometry of moraines indicate that successive glaciations of the Western Arthur Range have become progressively less extensive through the middle Pleistocene cycles.

Severe cooling during the middle Pleistocene has been recorded in the ODP Site 1119 sediment core (Southwestern Pacific) at ~ 430 ka, that is, MIS 12 (Carter and Gammon, 2004). A clear relationship on millennial-scale climatic variations between Antarctica, the mid-latitude New Zealand Southern Alps, and the oceanic oxygen isotopic record during the past 370 ka has been proposed by these authors.

Conclusion

Significant advances in knowledge of the middle Pleistocene glaciations in South America, New Zealand, and Tasmania have been achieved during recent years. Geomorphological mapping, mostly based on DTM tools, as well as cosmogenic radionuclide dating, was undertaken in several regions and then correlated with limnological studies from the Andean lakes, with marine $\delta^{18}\text{O}$ isotope curves, as well as with Antarctic temperature curves. In Patagonia, volcanic sequences interbedded with lava flows have proved useful for constraining the glacial chronologies with the use of $^{39}\text{Ar}\text{--}^{40}\text{Ar}$ dating techniques. The new radionuclide cosmogenic dating techniques applied by Hein et al. (2009) on cobbles from pre-LGM outwash plains, instead of eroded boulders, offer huge opportunities for the establishment of chronologies in those areas where surface boulders, lava flows, or organic matter are unavailable. Concentration depth profiles supported the cosmogenic ages and suggest erosion rates on the terraces, as well as the moraine degradation rates when the results are compared with surface boulders age.

Kaplan et al. (2007) have questioned the suitability of cosmogenic nuclide dating as a chronometer for pre-LGM deposits in southern South America and Tierra del Fuego. They have suggested that this dating technique is not so effective in

the Lago Buenos Aires region. As most of the exposure surface ages obtained from boulders on middle Pleistocene moraines gave LGM ages, they hypothesized that higher rates of exhumation, boulder weathering, and landscape change had occurred further to the south during the Quaternary. This was perhaps influenced by the more oceanic and subantarctic climates. The effect of the hyperhumid climate-derived erosion in the mountains of New Zealand has also been used to explain the relative scarcity of pre-LGM glacial features. It seems that aridity in the tropical and central Andes, and on the eastern slope of the Southern Andes, has helped to preserve glacial landforms and to restrict chemical weathering on the exposed glacial boulders. This explains the suitability of the cosmogenic radionuclide techniques for constraining middle Pleistocene chronologies in those particular environments.

During the last 0.8 Ma, glacial advances have been triggered in the Southern Hemisphere in the high mountains and close to present sea level in subantarctic latitudes. Although the full correspondence between glacial advances during the oldest middle Pleistocene glaciations is not yet clear, glacial evidence from MIS 12 to 4 is clearly identified in several glaciated valleys of South America and the Southern Pacific Islands. Although many similar cosmogenic ages were found for glacial sequences in Tasmania and Lago Buenos Aires, according to Rother et al. (2010), the resulting depositional glacial sequences in the maritime-climate New Zealand Alps may differ from those of drier, higher latitudes and higher elevation glacier systems in the Southern Hemisphere. A more complete dataset is still required to compare those environmentally similar mountain regions in the Southern Hemisphere. Moreover, the evidence available indicates that the middle Pleistocene glaciations occurred in phase with those in the Northern Hemisphere during the period dominated by the 100 ka orbital cyclicity period.

Late Pleistocene Glacial Events in Beringia

S A Elias, Royal Holloway, University of London, Egham, UK

© 2013 Elsevier B.V. All rights reserved.

Late Pleistocene glaciations in Beringia included rapid expansion of valley glaciers directly after the last interglacial interval (marine isotope stage (MIS) 5e). Glaciation during MIS 4 is referred to as the Early Wisconsin in North America and the Zyryan in northeastern Russia. With the exception of the Alaska Range and Chugach/St. Elias Mountains, the MIS 4 glacial ice caps and mountain glacier complexes throughout much of Beringia were considerably more extensive than during the subsequent Late Wisconsin/Sartan glaciation in MIS 2.

Introduction

The region of the western Arctic stretching from the Lena River in northeast Russia to the Mackenzie River in Canada is geographically known as Beringia. From a glaciological standpoint, Beringia, including the vast continental shelves of the Bering and Chukchi Sea, has presented a great anomaly throughout the Cenozoic. While nearly all other high-latitude regions of the Northern Hemisphere were covered by ice sheets during each glaciation, the lowlands of Beringia remained free of ice, thus providing a refuge for high-latitude flora and fauna. Owing to the buildup of continental-sized ice sheets over mountain ranges in North America, Greenland, parts of Eurasia, and other regional mountain ranges during Pleistocene glaciations, global sea level repeatedly dropped significantly, exposing large portions of the continental shelves. For instance, during the last glaciation, global sea-level dropped by 120–130 m (Clark et al., 2009; Lambeck et al., 2002), exposing the continental shelf regions of the Bering and Chukchi seas between Siberia and Alaska. These vast shelves lie only about 30–110 m below modern sea level. Therefore, as continental ice sheets grew, sea-level dropped, and the shelf regions between NE Russia and Alaska became dry land forming the Bering land bridge. By mapping the 120 m contour of the sea floors for the Bering and Chukchi seas (without compensation for gravitational, deformational, and rotational perturbations in sea level, see Milne and Mitrovica, 2008), it is possible to roughly trace the outline of the former land bridge region (Figure 1). This land bridge was no narrow isthmus between two continents. Rather, from north to south, the land bridge extended more than 1000 km and may have existed for more than 10 000 years (from 32 000 to 18 000 years ago) during the last glacial advance. From east to west, the land bridge was narrow at the center (in the Bering Strait region) but quite broad at both the north and south ends. The area of the land bridge was larger than the state of Texas.

When it existed, the Bering Land Bridge cut off circulation between the waters of the North Pacific and Arctic oceans with global influences on thermohaline circulation and climate (Hu et al., 2010). Regionally, the presence of this vast land bridge increased continentality and diminished the inland

flow of relatively warm, moist air masses from the North Pacific. Beringia was also influenced by being downwind of large ice sheets in Scandinavia and the Eurasian north, which themselves created widespread aridity during full glacial conditions (Siegert et al., 2001; Figure 1). Moisture stripped from the westerlies by these ice sheets left little but strong dry winds to sweep the landscapes of Beringia. Consequently, despite being cold enough to accumulate glacial ice, the desiccating environment of the land bridge restricted glaciation to isolated mountain ranges and kept glacial ice out of the lowlands of Alaska, the Yukon, and eastern Siberia, plus the land bridge itself. The largest of the alpine glacier complexes was, in fact, the westernmost extension of the Cordilleran Ice Sheet that once occupied western North America. This ice sheet covered the Alaska Range, and extended south and west to the Alaskan Peninsula and the continental shelf regions of Prince William Sound and the Gulf of Alaska (Kaufman et al., 2011; Mann and Hamilton, 1995). The Beringian lowlands remained ice-free throughout the Pleistocene.

Beringia is most conveniently partitioned for discussion into three geographic sectors: western Beringia, central Beringia, and eastern Beringia. Western Beringia is comprised of the regions of northeast Russia, from the Verkhoyansk Mountains in the west, to the Bering and Chukchi Sea coasts in the east, and the Sea of Okhotsk in the south. The Verkhoyansk Mountains lie along the eastern margin of the lower Lena River Basin and form the western limit of some characteristic Beringian plant taxa. The central sector of Beringia is that area of the Bering Land Bridge that is now submerged beneath the Bering and Chukchi seas, forming what was once a broad, relatively flat landscape with only a few highlands (the modern islands of the northern Bering Sea region). Eastern Beringia is defined as the unglaciated regions of Alaska and the Yukon. The eastern boundary of Beringia has been considered to be the lower Mackenzie River in the Canadian Northwest Territories (Hopkins, 1982). This places the eastern edge of Beringia along the margin of the Laurentide ice sheet at its maximum extent.

The vast regions of Beringia contained enormous topographic diversity, spanning over more than 20° of latitude and 80° of longitude (Figure 1). One of the principal differences between western and eastern Beringia is that the former region is topographically more complex and rugged than the latter (Brigham-Grette et al., 2004). The northward-draining river basins of the Lena, Indigirka, and Kolyma are broken by steep mountain ranges, as well as broad uplands. The geography of Eastern Beringia is marked by three sets of mostly east-west trending mountain ranges. From south to north, these comprise (1) the Pacific coastal ranges that continue southwest along the Alaska Peninsula, (2) the Alaska Range, about 100 km inland from the Gulf of Alaska, and (3) the Brooks Range, separating the interior lowlands from the North Slope

Figure 1 Map of northeast Asia and northwestern North America, showing the regions of western and eastern Beringia, and the Bering Land Bridge.

region. The interior regions of Alaska and the Yukon lie in the rain shadow of two high mountain ranges, which block Pacific moisture.

Contrasts in Paleoclimate Across Eastern and Western Beringia

During the past 20 years, cooperation between Russian and North American scientists has added significantly to our understanding of Beringian paleoenvironments, especially concerning the last glaciation. For instance, we have learned that there were significant differences between the climate and vegetation of western versus eastern Beringia during the marine isotopic stage 3 interstadial (MIS 3, ca. 48–28 ka). In western Beringia, temperatures apparently rose to nearly modern levels, allowing treeline to migrate northward and into mountain ranges to virtually its modern limit (Anderson and Lozhkin, 2001). In contrast to this, however, very little evidence exists for the expansion of coniferous forest in eastern Beringia during MIS 3. Based on fossil beetle evidence, there appears to have been different degrees of warming in the northern and southern sectors of eastern Beringia during this interstadial (Elias, 2001). The Arctic regions experienced mean summer temperatures as much as 1.5 °C warmer than modern levels at about 35 ka, whereas the synchronous warming in subarctic regions remained about 2 °C cooler than modern levels.

As in other high-latitude regions, the Last Glacial Maximum (LGM) was an interval of climatic cooling. Paleotemperature estimates based on fossil beetle assemblages (Elias, 2001) suggest that average summer temperatures (T_{MAX}) were as much as 7.5 °C cooler at 22 ka than they are today in the Yukon. However, it appears that this cooling of summer temperatures was far from uniform across Beringia. On the Seward Peninsula, for instance, T_{MAX} was depressed by a maximum of 2.9 °C.

Most eastern Beringian paleotemperature estimates based on LGM beetle data fall within a range of 3–5 °C colder than modern T_{MAX} . Mean January temperatures (T_{MIN}) in eastern Beringia were probably depressed by very little, if at all (Elias, 2001). The fossil beetle evidence (Alfimov and Berman, 2001) indicates that LGM summer temperatures in western Beringia were essentially as high as they are today in many regions, and T_{MIN} values remained close to modern levels as well. However, not all researchers agree on these temperature reconstructions. For instance, periglacial features that developed during the LGM indicate that mean annual temperatures dropped significantly (Hopkins, 1982). Most paleoclimatologists agree that on a very broad scale, Beringia was relatively dry and cold with cooler summers during the LGM. More mesoscale patterns indicate east to west trends in temperature and moisture gradients with colder and drier conditions dominant over eastern Beringia (Brigham-Grette et al., 2004). Guthrie (2001) postulated that during the LGM, western Beringia was kept arid by a huge, stable, high-pressure system north of the Tibetan Plateau. North Atlantic sea-ice cover and the Scandinavian/Eurasian ice sheets would have cut off the main source of westerly moisture, enhancing aridity in Asiatic steppe regions. Lowered sea level and the Cordilleran Ice Sheet would have reduced the moisture available to interior regions of eastern Beringia.

Sea-Level History

Six marine raised beaches have been documented along the more stable parts of the Alaskan coastline providing evidence that sea level was higher than that during some earlier interglacial warm periods. The oldest four high sea-level events occurred during the late Pliocene to middle Pleistocene and are significant with respect to paleoclimate (Kaufman and Brigham-Grette, 1993). The two late Pleistocene high stands

Table 1 Timing of major late Pleistocene cold events and marine transgressions in Beringia

Cold event	W. Beringian terminology	E. Beringian terminology	Age (calibrated year BP $\times$ 1000)	Marine transgression event
Middle MIS 5			125 to >100 100–88 <88 to >70	Pelukian Simpsonian
MIS 4	Zyryan glaciation	Early Wisconsinan glaciation	70–55	
MIS 2	Sartan glaciation	Late Wisconsinan glaciation	25–15	

are known as the Pelukian transgression, dated between 125 000 and 115 000 years BP (MIS 5e), and the Simpsonian transgression, dated between about 88 000 and 70 000 years BP (MIS 5a; [Table 1](#); [Brigham-Grette and Hopkins, 1995](#); [Brigham-Grette et al., 2001](#)).

The last interglacial, or MIS 5, broadly includes the period from about 130 000 to 75 000 years. The time period is normally characterized as including the peak of the last interglacial (MIS 5e) followed by two mild and two cooler intervals (MIS 5d through a) which eventually terminated in the first of the two major glacial intervals, MIS 4 ([Figure 2](#)). The peak of the last interglacial, MIS 5e with insolation at +11% of modern values, is remarkable across Beringia because the Bering Strait was submerged; the relative sea level along the Bering Strait coast stood roughly 6–7 m higher than it is today, and terrestrial climates were generally warmer. In the Bering and Chukchi seas, it has been estimated that for much of this interval, winter maximum sea-ice limits were as much as 800 km further north, well north of the narrow Bering Strait; summer sea ice was also less extensive and marine mollusks from the Bering Sea extended their range to Barrow, Alaska ([Brigham-Grette and Hopkins, 1995](#); [CAPE Last Interglacial Project Members, 2006](#); [Polyak et al., 2010](#)). Similar range extensions have been documented in marine sediments on the Russian coast and confirmed with the expansion of species of foraminifer from northern Japan as far north as eastern Chukotka ([Brigham-Grette et al., 2001](#)). Treeline spread to the Russian coast across most of western Beringia with range extensions among some tree species of 600–1000 km ([Lozhkin and Anderson, 1995a](#)). At the same time, in Alaska, the northward shift of treeline was more modest but extended at least 50 km north of the Brook Range ([Brubaker et al., 2005](#)). Temperatures estimates based on pollen and fossil beetle assemblages across the interior of Alaska suggest that summer temperatures were similar to today, but conditions were considerably wetter ([CAPE Last Interglacial Project Members, 2006](#); [Muhs et al., 2001](#)). In general, across Beringia, summer temperatures were 0–2 °C warmer, winters a few degrees cooler, and conditions were generally wetter.

Rapid Onset of Glaciation During MIS 5

Numerous workers have now documented that parts of the high arctic can become rapidly glaciated at the end of interglacials while eustatic sea level is still high. The Beringian region is no exception. Various researchers, including [Pushkar et al. \(1999\)](#), demonstrated that the mountains to the north and west of Kotzebue Sound had to have been rapidly glaciated

Figure 2 Relative sea-level curve for the last glacial cycle for Huon Peninsula, Papua New Guinea, supplemented with observations from Bonaparte Gulf, Australia. Error bars define the upper and lower limits. Time scale is based on U-series ages of corals older than about 30 ka and on calibrated ^{14}C ages of the younger corals and sediments. Reproduced from [Lambeck K, Esat TM, and Potter E-K \(2002\) Links between climate and sea levels for the past three million years. *Nature* 419: 199–206.](#)

near the end of MIS 11 (possibly stage 9). Such an explanation was necessary to explain the continuous deposition of extensive prodeltaic interglacial marine sediments overlain by glacially deformed glaciomarine muds. Because these deposits lie some 400 km from the edge of the shallow continental shelf, eustatic sea level had to have remained high as a consequence of widespread glaciomarine sedimentation in Kotzebue Sound in front of thin but extensive valley glaciers emanating from the western Brooks Range.

Research in Chukotka ([Brigham-Grette and Hayden, 2002](#); [Brigham-Grette et al., 2001](#)) and parts of southwest Alaska ([Kaufman et al., 1996, 2001](#)) has led to the realization that these regions also experienced rapid valley glacier expansion at times directly after the peak of MIS 5e. On outer Chukotka near the narrow Bering Strait, [Brigham-Grette et al. \(2001\)](#) re-assigned the Pinakul Formation, once thought to be of early Pleistocene age, to MIS 5a–e. The depositional sequence consists of an upward shallowing interglacial marine sequence characterized by warm faunas (the lower Pinakul Formation of MIS 5) overlain by a thin coarse gravel buried beneath a thick glaciomarine sequence containing classic drop stones (upper Pinakul Formation). The entire sequence is capped by glacial till, dated to MIS 4. [Brigham-Grette et al. \(2001\)](#) interpreted the section to represent 5e marine deposits overlain by an unconformity and then the rapid deposition of glaciomarine

sediments in MIS 5d. Deposition of such a thick section of glaciomarine mud in the shallowest coastal reaches of the Bering Strait requires that eustatic sea level remained near modern levels as rapidly expanding valley glaciers in coastal mountains reached the sea. Dating of the deposits is based on amino acid age estimates, radiocarbon, U/Th ages on concretions, and electron spin resonance (ESR) ages.

Valley glaciers responded in a similar fashion at roughly the same time in the Bristol Bay region of southwestern Alaska. Kaufman et al. (2001; Kaufman and Manley, 2004) demonstrated that mountain glaciers extended as much 100 km from their cirques and intersected the sea before eustatic sea level had dropped. Like the Pinakul sequence, this advance likely occurred either at the MIS 5e/5d transition or the MIS 5a/4 transition, based on stratigraphic relationships with the underlying Old Crow Tephra (ca. 140 ka) and a thermoluminescence (TL) age estimate of $70 \text{ ka} \pm 10$ on basalt overrun by advancing glacier ice. Calibrated amino acid age estimates and infrared-luminescence ages, however, offer the best geochronological control.

Stauch and Gualtieri (2008) used infrared stimulated luminescence (IRSL) dating of overlying cover sediments and ^{10}Be and ^{26}Al ages from moraine boulders in an east–west transect of Western Beringia, from the Verkhoyansk Mountains in the west to the Anadyr Uplands and Wrangel Island in the east. They documented glacial advances in the Verkhoyansk Mountains in MIS 5d, 5b, and possibly, MIS 4. The most recent glaciation in this region took place earlier than 50 000 years ago.

The rapid glacierization in Beringia at the end of MIS 5 was presumably driven by a precipitous drop in insolation while oceanic temperatures remained warm and eustatic sea level remained relatively high. However, changes in oceanic circulation also contributed to the onset of widespread Arctic glaciation in sensitive regions. Marine evidence suggests that major climate shifts such as the MIS 5e/5d transition also were driven by changes in deep water flux (Adkins et al., 1997; Kageyama et al., 2010). There is evidence for a rapid reorganization of deepwater production at the 5e/5d transition over a period of less than 400 years (Adkins et al., 1997). Hemispheric changes in the ocean and atmospheric system likely contributed to the rapid buildup of the Eurasian Ice Sheet at the 5e/5d transition (Krinner et al., 2011). Reconstructions of the Barents and Kara Ice sheets at this time suggest that the glaciers came onto shore and dammed large proglacial lakes in the Ural Mountains as early as 85–90 ka cal years BP (Mangerud et al., 2001). Ice sheets then retreated northward and readvanced in stage 4 to the Markhida Moraine by about 60 ka cal years BP.

Changes in the height and extent of the Scandinavian and Barents/Kara sea-ice sheets likely had a significant influence on the temporal and spatial response of the eastern Siberia and western Beringia (NE Siberia) to hemispheric scale climate change. Ice sheet and general circulation modeling (GCM) of the Scandinavian and Eurasian ice sheets by Siebert and Marsait (2000) suggests the extent to which changes in the size of these ice sheets likely diminished the temperature and precipitation influence of the North Atlantic eastward across the Russian arctic. Fine-tuned models of ice sheet size for parts of the late Pleistocene (Siebert et al., 2001) allow for more realistic assessments of how the physical stratigraphy of

western Beringia may have been influenced by ‘downwind’ effects while being upwind of the maritime influences of the Bering Strait and the sea-ice conditions in the Bering Sea.

The timing of ice sheet growth in Eurasia and Beringia fits well with the notion for early ice buildup over parts of the Canadian Arctic at this same time (Brigham-Grette and Hopkins, 1995). In Northern Alaska along the Beaufort Sea coast, the Flaxman glaciomarine deposits are dated to substage 5a (Carter et al., 1991). It is also well known and mapped below 7 m altitude on the Alaskan Arctic Coastal Plain (Brigham-Grette and Hopkins, 1995) recording both a high sea-level event that flooded the Bering Straits and the *Heinrich-like* collapse into the Beaufort Sea via Amundsen Gulf of a large ice sheet building over the Canadian Arctic islands, presumably starting in stage 5d. Erratics in the Flaxman beds are exclusively of Canadian provenience, reaching all the way to the Chukchi Sea coast of Alaska. TL ages on sediments, several ESR ages on shells, and a uranium-series age on whale bone, all place the age of the sediments at about 75 ka BP. The presence of the large whale bones in these deposits east of Barrow is especially significant since it requires that the Bering Strait was submerged enough (sea level above –55 m) to allow for the seasonal migration of bowhead and gray whales from the open Pacific, as they do today.

Flooding of the Bering Strait in MIS 5a, coupled with high insolation, may have contributed to the collapse of these Canadian and Eurasian ice sheets. The collapse of these ice sheets may have then allowed the penetration of moisture across the continent, permitting the expansion of valley glaciers in the Bering Straits region and elsewhere in the high latitudes. Afterward, increasing continentality, sea-ice cover, and the expansion of the Scandinavian/Eurasian ice sheet began to limit the available moisture supply across most of Beringia.

Early Wisconsin/Zyryan Glaciation (MIS 4)

Glaciation during MIS 4 is referred to as the Early Wisconsin in North America and the Zyryan in northeastern Russia, using traditional time stratigraphic terms. With the exception of the Alaska Range and Chugach/St. Elias Mountains facing the Gulf of Alaska, the Early Wisconsin/Zyryan glacial ice caps and mountain glacier complexes throughout much of Beringia were considerably more extensive than during the subsequent Late Wisconsin/Sartan glaciation in MIS 2 (Figure 3). Satellite and aerial photo mapping followed up by field studies of moraine limits across much of Chukotka indicates that Zyryan glaciers advanced 50–200 km from their source areas during MIS 4 (Heiser and Roush, 2001). Glushkova (1995, 2011) suggested that nearly 40% of Chukotka was covered with ice during this interval and in general, glacial advances were up to three times more extensive than during the Sartan glaciation. On the southeast corner of Chukotka, mountain glacier complexes coalesced into a piedmont lobe of sufficient size that the glacier terminated on St Lawrence Island leaving a moraine belt mappable on the sea floor (Brigham-Grette et al., 2001). Stauch and Gualtieri (2008) concluded that the penultimate glaciation had been the most extensive throughout Western Beringia. In some regions (i.e., the Koryak Mountains), this glacial advance apparently took place in MIS 4, while in the Verkhoyansk Mountains, and in the Pekulney Mountains, the

Figure 3 Map of western Beringia, showing the extent of glaciers during the Zyryan glaciation. Reproduced from Brigham-Grette J, Lozhkin AV, Anderson PM, and Glushkova OY (2004) Paleoenvironmental conditions in Western Beringia before and during the Last Glacial Maximum. In: Madsen D.B. (ed.) *Entering America. Northeast Asia and Beringia Before the Last Glacial Maximum*, pp. 29–61. Salt Lake City: University of Utah Press.

Tanyurer River Valley, and in Kamchatka, the penultimate glaciation apparently took place in MIS 5 and MIS 6, respectively.

Correlation between Zyryan glacial events in western Beringia and Early Wisconsinan glacial events in eastern Beringia can be difficult (Heiser and Roush, 2001) because of dating problems. The ages of MIS 4 glacial advances in Beringia are most commonly based on morphostratigraphic relationships coupled with a variety of relative age estimate criteria, stream terrace stratigraphy, and most recently, cosmogenic isotopic dating.

New sediment records from Lake El'gygytyn ('Lake E') in the heart of Chukotka, NE Russia, provide evidence of time-continuous paleoclimate change over the past 350 000 years (Brigham-Grette et al., 2007). It is located 100 km north of the Arctic Circle in Chukotka, NE Russia (Figure 4), and was produced by a meteorite impact 3.6 million years ago during the warm mid-Pliocene geological period. When the meteorite hit, the Arctic was exceedingly different from today, with mean annual temperatures $\sim 12^\circ\text{C}$ warmer and global averages $3\text{--}4^\circ\text{C}$ warmer than today (Lunt et al., 2009). At that time, most of the Arctic borderlands were heavily forested, the Arctic Ocean lacked permanent sea ice, and the Greenland Ice Sheet did not exist, at least not in its present form (Brigham-Grette and Carter, 1992; Miller et al., 2010). In fact after the impact, a million years passed before the onset of the first major glaciation of the Northern Hemisphere. The El'gygytyn Crater is unique, having formed in the center of what was to become Beringia – the largest contiguous landscape in the Arctic to escape continental scale glaciation. Pilot cores from Lake E document regional changes in paleoclimate reflected by changes from cold-dry to cold wet episodes during glaciation to warm-wet interglacial intervals (Melles et al., 2007). The last interglacial (MIS 5e) at this site is exceptionally warm, consistent with the idea that tundra was nearly absent from western Beringia during this time (Lozhkin and Anderson 1995a; Lozhkin et al., 2007). This nonglacial record provides the first continuous record of multiple glacial and interglacial cycles from the western Arctic (Brigham-Grette et al., 2007 and papers therein;

Figure 4 Location of Lake El'gygytyn, 100 km north of the Arctic Circle in northeastern Russia. (a) Location of Lake El'gygytyn relative to other key lacustrine basins in Beringia with long sediment records including Elikchan Lake (65 ka; Lozhkin and Anderson, 1995b); Imuruk Lake (130 ka; Colinvaux, 1964); Squirrel Lake (180 ka; Berger and Anderson, 2000); and Ahaliork Lake (130 ka; Eisner and Colinvaux, 1990; Anderson and Brubaker, unpublished). Figure 5). Glacial intervals suggest variable cold and dry conditions consistent with tundra steppe conditions.

Several glacial advances have been documented in Alaska between the middle and late Pleistocene. Among the most distinctive features of these glaciations are the Salmon Lake moraines of the Kigluaik Mountains of the Seward Peninsula, Alaska (Kaufman and Calkin, 1988; Figure 6). The moraines of the Itkilik I stage in the Brooks Range are also thought to represent MIS 4 glaciation (Hamilton, 1986). Ice advanced onto St. Lawrence Island, north of the Bering Strait, some time in the late Pleistocene. A stratigraphic study of sedimentary sequences on the island indicates that this glaciation occurred after the last interglacial and before the Late Wisconsinan glaciation, so it seems most likely that it occurred in MIS 4 (Heiser and Roush, 2001).

Cosmogenic exposure ages of moraine boulders from sites in the Alaska Range and Ahklun Mountains that are associated with the penultimate glaciation have shown that this advance culminated between 60 000 and 50 000 years ago (Briner and Kaufman, 2008). In the northern Alaska Range, ^{10}Be ages from moraine boulders indicate that the MIS 4 glaciation stabilized between 58 000 and 52 000 years ago (Kaufman et al., 2011).

Figure 5 July insolation at 67.5° N (Paillard et al., 1996) and stacked marine oxygen isotope record (Martinson et al., 1987) with isotopic stages and substages for the past 260 ka, plotted versus the major biogeochemical proxies in core PG1351 from Lake El'gygytyn according to the age model presented in Nowaczyk et al. (2007). The peak warm (unit 1), normal warm (unit 2), cold and dry (unit 3), and cold but more moist (unit 4) climate modes. Figure 6 Ridge of the Early Wisconsin Salmon Lake moraine exiting Cobblestone Creek, Seward Peninsula. Photo by Brigham-Grette.

The ages of penultimate glacial moraines in the Brooks Range have not yet been dated, but likely are of similar age as they postdate the Old Crow tephra, which is now thought to have been deposited in MIS 6 (Hamilton, 2001). But in the Bristol Bay region of southwest Alaska, the penultimate advance appears to have culminated in late MIS 5 (Kaufman and Thompson, 1998).

¹⁰Be ages from moraine boulders from high-elevation sites in the Anvil Range and Pelly Mountains of the Yukon indicate that these areas were ice-covered before the McConnell (Late Wisconsin) glaciation and that they became ice-free ~30 000 years before the present (Stroeven et al., 2010). This places a likely MIS 4 age for this glacial advance. Ward et al. (2007) also found evidence for an MIS 4 glacial advance in the Aishihik area of southwestern Yukon. Cosmogenic ages on boulders on the penultimate drift ranged from about 54 000 to 51 000 years ago. They proposed that this glacial advance be termed the 'Gladstone glaciation' in the Yukon. This correlated well with the Icefield glaciation defined from glacial deposits in the nearby St. Elias Mountains of southeastern Alaska.

Paleotemperature estimates for MIS 4 in Eastern Beringia are indicative of cold summers. T_{MAX} cooling of 6 °C below modern levels has been estimated from beetle assemblages in Alaska and the Yukon (Elias, 2001). However, T_{MIN} values were estimated to be near modern levels. This seasonal temperature profile would aid the growth of mountain glaciers, as colder summer temperatures would inhibit summer melting of snowpack, and winter temperatures at these high latitudes have been sufficiently low to allow glacial ice to form, throughout the Pleistocene.

Middle Wisconsin/Karaginsky Interstadial

The Beringian interstadial warming associated with MIS 3 is known as the Karaginsky interstadial in western Beringia and as the Middle Wisconsin interstadial in eastern Beringia. During this interval, glacial margins retreated throughout Beringia. As discussed earlier, the paleobotanical evidence from western Beringia indicates warmer than modern conditions there during this interval, especially in the Arctic. Fossil beetle evidence (Sher et al., 2002) indicates that T_{MAX} was 1–3 °C warmer than modern in the Arctic and that T_{MIN}

was lower than modern, pointing toward increased continentality during the Karaginsky interval. This level of interstadial summer warming apparently did not occur in eastern Beringia. The fossil beetle evidence suggests that early MIS 3 environments had T_{MAX} values about 3 °C colder than modern and T_{MIN} values about 3 °C warmer than modern. This reconstruction fits well with both the summer and winter insolation pattern at the beginning of stage 3, about 60 000 years BP. Younger (stratigraphically higher) stage 3 samples from the Yukon yielded T_{MAX} closer to modern values, with T_{MIN} values remaining warmer than present. Eastern Beringian samples dated between 32 400 and 29 600 years BP are indicative of mean summer temperatures that were 1–4 °C colder than today.

Paleobotanical evidence from eastern Beringia shows some expansion of coniferous forests in interior regions, but not approaching modern northern treeline in Alaska. The warmest interval of the interstadial documented in the vegetation comes from interior Alaska. The 'Fox Thermal Event,' dated from 35 000 to 30 000 ¹⁴C years BP, is associated with expansion of spruce-forest tundra (Anderson and Lozhkin, 2001).

Late Wisconsin/Sartan Glaciation

The last Pleistocene glaciation in western Beringia is called the Sartan glaciation. The lack of significant moisture across Beringia during the LGM prevented the growth of large ice masses. As shown in Figures 7 and 8, the Sartan and Late Wisconsin ice limits were well inside those of some previous glaciations. LGM glaciation in western Beringia was essentially limited to valley and cirque glaciation in some mountain ranges (Brigham-Grette et al., 2003). Glacial extent decreased from west to east in western Beringia, probably because of increasing aridity toward the Bering Strait region. The Verkhoyansk Mountain region developed glacial ice that extended downslope almost to the Lena River (Figure 8; Stauch and Gualtieri, 2008; Zamoruyev, 2004). Radiocarbon dating of wood and organic matter, combined with cosmogenic isotope surface exposure ages, indicates that LGM ice in western Beringia reached its maximum extent between 27 000 and 20 000 cal years BP (Brigham-Grette et al., 2003). A study of fossil diatom assemblages from Bering Sea sediment cores (Brigham-Grette et al., 2003) suggests that the Bering Sea experienced sea-ice cover for as much as 9 months per year during the LGM; Caissie et al. (2010) have refined this estimate to suggest the presence of perennial ice in the eastern Bering Sea during the LGM. The combination of Bering Sea ice cover and the 1000-km-long land bridge in the center of Beringia meant that Pacific moisture was far removed from the interior regions of Beringia during the LGM.

Late Wisconsin glaciers occupied about 726 000 km² of Alaska (Kaufman et al., 2011). The transition from MIS 3 to MIS 2 is imprecisely dated in eastern Beringia, but by about 32 000 cal years BP, the climate changed from interstadial to glacial, as evidenced by changes in regional floras and faunas. Apparently, the glacial advances in eastern Beringian mountain ranges were not synchronous. The Late Wisconsin advance began in the mountains of southwestern Yukon by 31 000 cal years BP (Hamilton and Fulton, 1994). The Cordilleran Ice

Figure 7 Map of eastern Beringia, showing the extent of glaciers during the Early and Late Wisconsinan glaciations. Reproduced from Manley WF and Kaufman DS (2002) *Alaska PaleoGlacier Atlas*. Sheet advanced throughout the coastal regions of the Pacific Northwest about 28 000 cal years BP. At that time, ice advanced in the Brooks Range, signaling the beginning of the Itkilik II glaciation (Hamilton and Ashley, 1993). Ice advances in the highlands of the Seward Peninsula are termed the Mount Osborne glaciation (Figure 9). In Denali National Park (Alaska Range), glaciers neared their late Wisconsin limit about 22 000 years ago and began retreating by about 19 000 years ago (Kaufman et al., 2011). LGM glaciers reached their maximum size in the Ahklun Mountains of southwestern Alaska about 24 000 years ago (Briner and Kaufman, 2008) and began retreating by about 20 000 years ago. In contrast to these chronologies, LGM ice margins in the Brooks Range were already retreating by 25 000 years ago. Likewise, evidence for stabilization of sand sheets and dunes in the Kobuk Dunes region of northwestern Alaska after 22 000 cal years BP suggests climatic amelioration that may correlate with the Port Moody Interstade documented from southwestern British Columbia (Clague et al., 2004).

During the LGM, the Cordilleran Ice Sheet covered southern and central Yukon and parts of southern Alaska (Figure 7), where it formed ice fields and large valley and piedmont glaciers, flowing out of the St. Elias Mountains, the Chugach Range, and the Alaska Range. The ice extended out onto the

continental shelf to the south and into the broad, low country drained by the Yukon River and its tributaries to the north (Mann and Hamilton, 1995). Ice expanded from the coastal mountains of British Columbia into the Alexander Archipelago of southeastern Alaska, reaching the outer continental shelf in some regions (Carrara et al., 2002).

One of the earliest dates for deglaciation following the LGM in eastern Beringia comes from the Hungry Creek site, Yukon. Hughes (1983) suggested that the western limit of Cordilleran ice began retreating here by about 19 000 years BP. Mann and Hamilton (1995) suggest that ice retreat was time-transgressive in southern Alaska, with northern shelf areas becoming ice-free by 16 000 years BP. Much of southeastern Alaska was deglaciated by about 15 000 cal years BP (Clague et al., 2004). Deglaciation in the Brooks Range began by at least 13 400 cal years BP (Hamilton, 1983). Postglacial environmental change throughout eastern Beringia brought about wholesale changes in vegetation, the regional extinction of much of the megafauna, and the entrance of *Homo sapiens*.

The Younger Dryas oscillation first documented in Northwest Europe and in the Greenland ice core stable isotope records was expressed to greater or lesser degrees in the Alaska glaciological record. Briner et al. (2002) dated glacial advances in the Ahklun Mountains to the interval 11 700–11 000 years

Figure 8 Map of western Beringia, showing the extent of glaciers during the Sartan glaciation. ago. Matmon et al. (2006) obtained ^{10}Be ages on moraines along the northern front of the Alaska Range that also date to this interval. But in other regions, such as the Brooks Range, there is little or no evidence for a Younger Dryas glacial advance (Hamilton, 2003).

Late Quaternary of the Southwest Pacific Region

D J A Barrell, GNS Science, Dunedin, New Zealand

© 2013 Elsevier B.V. All rights reserved.

This article is a revision of the previous edition article by E. Colhoun, J. Shulmeister, volume 2, pp. 1066–1076, © 2007, Elsevier B.V.

Introduction

The main land masses of the southwest Pacific region are the archipelago of New Zealand and the southeastern parts of Australia. To the south is the Southern Ocean, within which are several small sub-Antarctic islands. Southern parts of the region lie within the Southern Hemisphere belt of middle-latitude westerly winds, while northern parts lie within the influence of the subtropical high pressure belt. Glaciers formed on parts of New Zealand and southernmost Australia in the late Pleistocene during episodes of cold climate (glaciations). In the high mountain areas of New Zealand, much-reduced glaciers persisted into the Holocene and some of these glaciers still survive today.

The late Quaternary Period spans the last 130 000 years and comprises the late Pleistocene and Holocene epochs (Table 1). The Last Glaciation occurred between about 74 000 and 18 000 years ago and brought generally cooler conditions than prevail today. The coldest episodes (stadials) occurred in the early and late parts of the glaciation, separated by an interstadial period of generally less severe climate (Barrell, 2011; Suggate, 1990; Table 1). During stadials, glaciers formed in mountain areas of New Zealand, Tasmania, and the Snowy Mountains of southeastern Australia (Colhoun and Shulmeister, 2007). The Last Glaciation was succeeded by the Last Glacial–Interglacial Transition. This period of transition saw a steady improvement in temperatures, major adjustments of mountain and mountain-valley landscapes to the melting away of glaciers, the withdrawal of alpine and tundra vegetation to higher altitudes on mountain ranges, and the progressive expansion of forests. By the start of the Holocene, about 11 700 years ago, temperatures in New Zealand had risen to levels close to those of today (Alloway et al., 2007), and glaciers had retreated to the vicinities of the highest mountains (Gellatly et al., 1988). The climatic picture is less clear in Australia, due to difficulties in distinguishing between the effects of temperature and variable aridity on the biological indicators of climate (Turney et al., 2006).

This article describes the late Pleistocene glaciers of southern parts of Australia, and then examines the glaciers of New Zealand during the late Pleistocene and the Holocene. Brief mention is made of late Pleistocene glaciation on the main sub-Antarctic islands of the Australasian region; Auckland Island, Campbell Island and Macquarie Island (Figure 1).

In regard to the late Pleistocene and Holocene glacial history of the southwest Pacific, it is important to consider the dynamics of the plates that form the Earth's crust in this wide region. The boundary between the Indo-Australian Plate (commonly called the Australian Plate), and the Pacific Plate, lies beneath the Southwest Pacific Ocean, and passes through New Zealand on a northeast–southwest trend. As a result, New Zealand has a dynamic tectonic setting, with active volcanoes

in the central part of the North Island, recently uplifted ranges, and ongoing deformation and uplift of the Earth's crust, particularly in the South Island. In contrast, southern Australia and Tasmania lie on a continental platform, with landscapes that are much more stable than those of New Zealand. In the sub-Antarctic part of the region, Auckland and Campbell islands lie on a stable continental platform, away from the main locus of the active plate boundary through the New Zealand mainland islands. In contrast, Macquarie Island lies on a recently uplifted fragment of ocean floor crust, alongside the plate boundary.

Australia

The Snowy Mountains

The mainland of Australia, being relatively far north of the southern polar region, of relatively low altitude and, away from the coast, relatively dry, is an environment not conducive to the formation of glaciers, even during the coldest parts of the Last Glaciation. Only at Mt Kosciuszko in the Snowy Mountains (Figure 1) is there unmistakable evidence for late Pleistocene glaciers on the Australian mainland.

Mt Kosciuszko (2228 m; latitude 36°27'S) is Australia's highest mountain and the highest point on a broad range (massif) about 2000 m high and extending for about 120 km². The massif has ice-eroded cirque basins, some of which contain lakes, and there are also some short, ice-scoured valleys. In a few locations there are well-formed moraine loops marking the margins of former glaciers, notably at Blue Lake and Lake Cootapatamba (Figure 2).

Since the nineteenth century, scientists have offered differing opinions on the extents of ice-age glaciers on the Kosciuszko massif, and when they reached their maximum size(s) (David et al., 1901; Galloway, 1963). Barrows et al. (2001) made a geomorphological map of glacial landforms on the Kosciuszko massif, which showed that cirque and short valley glaciers, at their maximum extent as indicated by well-defined glacial landforms, covered only about 15 km². The map also highlighted evidence for at least two glaciations having affected the massif. In order to determine when these glacier advances took place, Barrows et al. (2001) measured the ages of 24 boulders resting on the surfaces of moraines at Blue Lake and Lake Cootapatamba, using the terrestrial cosmogenic nuclide (TCN) dating method. Based on chemical changes produced by cosmic radiation that penetrates the Earth's atmosphere, the TCN dating method involves measuring the amounts of cosmogenic isotopes in minerals from rock surfaces, in this case beryllium-10 (¹⁰Be) in quartz. The TCN ages given in this article are as reported in the original papers that are cited, and may not accord to present calibration standards. In contrast, radiocarbon calendar ages are recalculated according to

Table 1 Late Pleistocene and Holocene glacier activity in the SW Pacific region

<i>Geological epoch</i>	<i>Climate event</i>	<i>MIS stage</i>	<i>Approximate calendar age ($\times 1000$ years)</i>	<i>New Zealand</i>		<i>Snowy Mountains</i>	<i>Tasmania</i>
Holocene	Postglacial	1	0–11.7	Aranui Postglacial	'Neoglacial' events near modern glaciers	No glaciers	No glaciers
Late Pleistocene	Last Glacial–Interglacial Transition	2	11.7 to ~18.0		Late-Glacial ice advances		
	Last Glaciation	Late	~18.0 to ~28	Otira Glaciation	Late Otira Glaciation	Late Kosciuszko Glaciation	Episodes of glacier activity, no formal regional names applied
		3	~28 to ~59		Mid-Otira interstadial		
		Early	~59 to ~74		Early Otira Glaciation	Early Kosciuszko Glaciation	
Middle Pleistocene	Last Interglacial	5	~74 to ~130	Kaihinu Interglacial – indications of ice advance during cold stadials		No evidence preserved for glacier activity	Uncertain
	Penultimate Glaciation	6	Older than ~130	Waimea Glaciation – glaciers more extensive than in late Pleistocene			Glaciers more extensive than in late Pleistocene

The Marine Oxygen Isotope Scale (MIS) stages are from [Martinson et al. \(1987\)](#).

Figure 2 Last Glaciation moraines at Blue Lakes, Mt Kosciuszko area, Snowy Mountains, Australia. Reproduced from Barrows TT, Stone JO, Fifield LK, and Cresswell RG (2001) Late Pleistocene Glaciation of the Kosciuszko Massif, Snowy Mountains, Australia. *Quaternary Research* 55: 179–189, with permission (Figure 8 of Colhoun and Shulmeister, 2007).

the 2009 IntCal09 calibration (Reimer et al., 2009). The mapping together with the TCN dating indicates that the first and also the most extensive glaciation, known locally as the Early Kosciuszko Glaciation, produced a single glacier advance (Snowy River Advance) sometime between ~65 000 and ~55 000 years ago. The Late Kosciuszko Glaciation comprised three glacier advances, progressively less extensive. The first one, named the Headley Tarn Advance, occurred sometime between ~35 000 and ~30 000 years ago. Next was the Blue Lake Advance, sometime between ~21 700 and ~17 500 years ago, and last was the Mt Twynam Advance, sometime between ~18 200 and ~15 400 years ago (Barrows et al., 2001). Radiocarbon (^{14}C) dating of lake-floor sediments in Blue Lake shows that sometime between 16 770 and 15 060 calendar years ago, the ice had gone and the lake was in existence (from Barrows et al., 2001; recalculated). These results indicate that glaciers disappeared promptly from the Kosciuszko massif at the end of the Last Glaciation, and that Kosciuszko has remained ice-free ever since (Barrows et al., 2001, 2002).

Tasmania

Tasmania today is a large island separated from the Australian mainland by Bass Strait. The strait is shallow and was dry land during glaciations, when sea level was as much as 120 m lower than it is today. At such times, Tasmania was a large cape of the Australian mainland. Tasmania lies in the path of the mid-latitude westerly wind belt, and has a temperate maritime climate. The prevailing westerly winds bring wetter and cloudier conditions to the southwestern part of the island, and drier rain-shadow conditions to the northeast. The landscape is hilly with a few mountain ranges, and an extensive tableland, the Central Plateau, in northern central Tasmania. The highest peak is Mt Ossa (1617 m) on the western edge of the Central Plateau.

During the Last Glaciation, small ice caps, cirque glaciers and small valley glaciers formed on and around the highest mountains and ranges in Tasmania, and a small ice sheet grew on the western side of the Central Plateau (Figure 3). The extent of late Pleistocene ice was considerably less than during middle and early Pleistocene glaciations (Augustinus, 1999; Colhoun, 2004; Colhoun and Fitzsimons, 1990; Kiernan, 1990). In contrast to the Snowy Mountains, there is not an established set of names for glacial and interglacial events across Tasmania – instead, local names have been applied in areas where detailed studies have been done. For this reason, only the generalized terms early Last Glaciation and late Last Glaciation are used in the description below.

In southwestern Tasmania, late Pleistocene glacial features, such as ice-smoothed topography, cirques and moraines, abound in the vicinity of peaks that are more than about 1000 m above sea level, the southernmost examples being at Pinders Peak (latitude 43°30'S) in Southwest National Park. Northeastward across Tasmania, the altitude of mountains with associated glacial features becomes progressively higher (Colhoun et al., 1996; Peterson and Robinson, 1969). In northeastern Tasmania, the Ben Lomond plateau, at about 1400 m above sea level, lacks glacial features, except for a small cirque moraine at Tranquil Tarn (41°37'S) in a shaded south-east facing position at the southern tip of the plateau (Barrows et al., 2002). The eastward rise in altitude of glacial features mimics the present-day gradient of westerly-wind precipitation that decreases eastwards across Tasmania.

TCN dating is advancing the state of knowledge considerably with regard to late Pleistocene Tasmanian glaciers. It is turning out that, similarly to the Snowy Mountains, late Pleistocene ice in Tasmania was more extensive during early parts of the Last Glaciation. For example, in the eastern part of the Central Plateau, morainic boulders lying outside of well-defined late Last Glaciation moraines returned ages ranging

Figure 3 The extent of glaciers in west-central Tasmania during the latter part of the Last Glaciation. Lakes are in gray, glaciers are in light blue, and ice limits are in red, dashed where uncertain. Reproduced from Colhoun EA, Hannan D, and Kiernan KW (1996) Late Wisconsin Glaciation of Tasmania. *Papers and Proceedings of the Royal Society of Tasmania* 130: 33–45, with permission (Figure 7 of Colhoun and Shulmeister, 2007).

from ~53 000 to ~24 000 years (Fink et al., 2000). In southern Tasmania, a study by Mackintosh et al. (2006) at Broad Valley in Mt Field National Park obtained ages of between ~44 000 and ~40 000 years for moraine boulders beyond the late Last Glaciation moraines, while at Schnells Ridge on Mt Anne in southwestern Tasmania, Kiernan et al. (2004) reported ages of between ~141 000 and ~39 000 years for extensive moraines outboard of the late Last Glaciation moraines. These findings are in keeping with interpretations from Chamouni in the King River valley in the West Coast Range, where Fitzsimons et al. (1993) obtained a ^{14}C age of 48 700 years for wood overlying the Chamouni glacial deposits, implying that the glacial sediments were deposited during early phases of the Last Glaciation, or during a preceding glaciation.

Dating has also provided some surprises regarding the moraine sequences formed late in the Last Glaciation. Near Lake Margaret in the West Coast Range, the largest moraine ridge in Tasmania, known as the Hamilton End Moraine, was generally thought to mark the late Last Glaciation ice limit (Colhoun, 1985), but TCN dating by Barrows et al. (2002) has returned

ages ranging from ~350 000 to ~190 000 years. This moraine therefore formed in the middle Pleistocene, whereas the late Pleistocene ice limit was about 1 km up-valley at the Poets Hill moraines, which are between ~19 000 and ~16 000 years old based on TCN measurements by Barrows et al. (2002).

In the West Coast Range at Dante Rivulet in the King River catchment, a buried soil horizon that is ~21 000 ^{14}C years old is overlain by glacial outwash sands and gravels containing wood fragments ~19 000 ^{14}C years old (Gibson et al., 1987). This indicates that late Last Glaciation ice appeared in this catchment between ~25 000 and ~22 000 calendar years ago. At Lake St Clair on the Central Plateau, TCN dating of late Last Glaciation terminal moraines enclosing the lake gave a wide spread of ages ranging from ~30 000 to ~17 000 years (Barrows et al., 2002). These ages are difficult to reconcile with ^{14}C dating of lake bed sediments from Lake St Clair near the terminal moraine complex, which indicates that the glacier retreated from its moraine complex, initiating the lake, ~18 450 ^{14}C years ago (~22 000 calendar years ago; Hopf et al., 2000). These

conflicting results indicate that the timing of late Pleistocene events at Lake St Clair needs further investigation.

TCN dating of several glacier systems across Tasmania indicates that late Last Glaciation terminal moraines formed between $\sim 20\,000$ and $\sim 17\,000$ years ago, with a few instances of outer parts of the moraine complexes dating from as long ago as $\sim 45\,000$ years (Barrows et al., 2002; Kiernan et al., 2004; Mackintosh et al., 2006). This suggests that in addition to the main late Last Glaciation ice maxima between $\sim 25\,000$ and $\sim 18\,000$ years ago, there may have been ice advances of similar extent in the middle part of the Last Glaciation, about $45\,000$ years ago. The TCN dating results also indicate that the main deglaciation occurred between $\sim 18\,000$ and $\sim 16\,000$ years ago, and that no ice survived in cirques after

about $15\,000$ years ago. In keeping with the results from the Kosciuszko massif, it appears that Tasmanian glaciers melted away rapidly at the end of the Last Glaciation, and Tasmania has been ice-free ever since (Barrows et al., 2002).

New Zealand

In New Zealand, small modern glaciers occur on Mt Ruapehu in the North Island at about latitude $39^{\circ}17'S$. In central to southern parts of the South Island's Southern Alps, modern glaciers occur from about latitude $42^{\circ}90'S$ to $45^{\circ}02'S$, with a few small perennial ice patches farther to the north and south (Chinn, 1995; Figure 4).

Figure 4 New Zealand location map (inset) and present-day topography of the South Island, showing rivers that were important conduits for ice-age meltwater, and locations mentioned in this article. The Australia–Pacific plate boundary (inset) comprises the Puysegur and Hikurangi subduction thrusts (teeth point down-dip) and the strike-slip Alpine Fault. Bathymetry is from GNS Science digital archives, with color changes at depths of 250, 750, 1500, 2500, and 4000 m. The onland digital elevation model is generated from 20 m-interval contours and spot heights from Land Information New Zealand digital data. Crown copyright reserved.

Like Tasmania, New Zealand lies in the path of the mid-latitude westerly-wind belt. The interaction between the prevailing westerly winds and the mountain ranges of New Zealand produces a strong orographic precipitation pattern, especially across the Southern Alps. As a result, the climate is very wet on the western side of mountains and much drier to the east. The modern glaciers occur where the mountains are high and the annual precipitation is relatively large.

During late Pleistocene glaciations, immense ice fields formed in the Southern Alps, and glaciers developed on many of the taller ranges of the South Island. There were also small glaciers on the higher ranges of the North Island. In New Zealand, the Last Glaciation is known as the Otira Glaciation (Suggate, 1990). A major ice advance early in the glaciation, approximately 65 000 years ago, is known as the Early Otira Glaciation, while later resurgences of the glaciers, between about 30 000 and 18 000 years ago, mark the Late Otira Glaciation (Alloway et al., 2007; Suggate and Almond, 2005; Figure 5). There is evidence suggesting that there may also have been major ice advances during the mid-Otira period, between about 50 000 and 30 000 years ago, preserved in Aurora Cave in Fiordland (Williams, 1996; see Figure 4), and in South Westland (Almond et al., 2001). Evidence has also been presented for major ice advances about 80 000 years ago, towards the end of the Last (Kaihinu) Interglacial period (Sutherland et al., 2007).

North Island

At the southern end of the Taupo Volcanic Zone are three tall, active volcanoes, from northeast to southwest, Mounts Tongariro (1967 m), Ngauruhoe (2287 m) and Ruapehu (2797 m) (Figure 4). Only Mt Ruapehu, the North Island's highest mountain, carries glaciers today, but on the mid to lower flanks of both Ruapehu and Tongariro are paired moraines formed by valley glaciers that flowed from ice caps on these mountains during late Pleistocene glaciations (Lee et al., 2011; Mathews, 1967; McArthur and Shepherd, 1990; Townsend et al., 2008; see Figure 5).

Although there is little direct information on the ages of the moraines themselves, radiometric dating of the volcanic rocks shows that much of Mt Tongariro is older than about 65 000 years (Hobden et al., 1996), and so has been in existence through the early and later phases of the Otira Glaciation. Accordingly, it has spectacular glacial valleys and lateral moraines, though somewhat modified by post-glacial volcanic activity. Mt Ngauruhoe is a near-perfect volcanic cone that has formed in the head of a formerly glaciated valley of the Tongariro massif. Ngauruhoe itself shows no sign of having been glaciated, which is consistent with its age of late Holocene (less than 6500 years; Lee et al., 2011). Mt Ruapehu has several well expressed glacial valleys on its eastern flank (Figure 6). The rocks forming the volcano's southern and eastern slopes are mostly between ~150 000 and ~120 000 years old (Gamble et al., 2003). This indicates that the glacial features, which must be younger than the rocks on which they rest, are probably no older than late Pleistocene. The western flanks of Ruapehu are mainly formed of lava flows younger than 50 000 years, but with many paired glacial moraines on the lowermost slopes. The extent to which these moraines were

formed by glaciers that flowed over these lava sheets during the Late Otira Glaciation, or whether some were formed earlier, and lava flows encroached to their margins subsequently, is yet to be established.

To the west, Mt Taranaki, also known as Mt Egmont (2518 m), is a near-perfect volcanic cone. The oldest rocks exposed on its slopes are about 18 000 years old, indicating that the volcano in its present form is primarily a post-glacial feature. No evidence for past glaciers has been found (Townsend et al., 2008).

Based on elevation and aspect, localized glaciers may possibly have formed on parts of the North Island axial ranges (Figure 5) during the Otira Glaciation, such as the highest parts of the Kaweka Range (~1700 m), the Kaimanawa Mountains (~1700 m), and the Ruahine Range (~1700 m), but no well-defined glacial landforms are evident.

On the Tararua Range, farther southwest along the North Island axial range, the existence of late Pleistocene ice-age glaciers is indicated by u-shaped valleys and cirque-like amphitheater basins in valleys draining the higher parts of the range (Adkin, 1911). The Park River valley, draining south off a peak called Arete (1505 m; 40°45'S), contains the best known example of a lateral moraine in the Tararua Range (Brook, 2009a).

South Island

Geographically, the name Southern Alps is applied to the main belt of high mountains that runs from southeast Nelson/west Marlborough to the Hollyford valley (Figure 4). Strictly speaking, mountain ranges around the periphery of the Southern Alps are regarded as entities that are separate from the Southern Alps, as is the Fiordland massif that forms the southwestern corner of the island.

Ranges in the northern parts of the South Island

Late Pleistocene glaciers formed on many of the taller mountain ranges in the northern part of the South Island, lying at the periphery of the Southern Alps, in northern Westland, Nelson, and Marlborough (Figures 4 and 5).

In the northwestern corner of the South Island are the Tasman Mountains, whose highest peaks range from 1500 to as much as 1800 m. Although ice-free today, the Tasman Mountains have numerous u-shaped valleys and cirque basins. These indicate that during glaciations, minor ice caps formed and glaciers extended down many of the mountain valleys (Figure 5). Terminal moraines are rarely preserved, and only tentative estimates can be made of how far the glaciers extended (Thackray et al., 2009). Recent studies have placed some limits on the extents of Otira Glaciation ice, both early in the glaciation at about 65 000 years ago, as well as during its late phase, culminating about 18 000 years ago (McCarthy et al., 2008), and the subsequent ice recession (Shulmeister et al., 2001, 2005).

Near the west coast, several of the higher ranges have glacial topography in the form of southeast-facing cirques and localized u-shaped valleys, such as in the Paparoa Range, where the highest peaks range from 1200 to 1500 m. An example from the Hohonu Range is illustrated in Figure 7, where the highest peaks are between 1200 and 1300 m.

Figure 5 An interpretation of the distribution of ice and the main vegetation zones at the maximum of the Late Otira Glaciation, between about 20 000 and 22 000 calendar years ago. The land extent approximates the 120 m isobath on the modern sea floor, reflecting lower global sea level at that time. Vegetation zonation, modified from Alloway et al. (2007), was originally based on McKinnon (1997) and Newnham et al. (1999), adjusted in detail to the topography. Late Otiran ice extent has been modified slightly from Alloway et al. (2007), as described by Barrell (2011). The ice map is generalized in its interior; it is likely that more bare rock was exposed than is depicted here. Modern ice is from Land Information New Zealand 1:50 000 scale digital data, and the present-day digital elevation model is generated from 20 m-interval contours and spot heights from Land Information New Zealand digital data, Crown copyright reserved.

Figure 6 Mt Ruapehu, the North Island's highest mountain, is an active volcano although much of its bulk dates from the Middle Pleistocene. As a result, Ruapehu carries many imprints of late Pleistocene glaciation. Just to the right of center, paired lateral moraines of the Wahianoa valley, probably of Late Otiran age, descend southeast from the upper slopes of the mountain. Although obscured by winter snow at the time this photograph was taken, small modern glaciers survive on the highest parts of the mountain. Mt Ngauruhoe, also covered in snow, lies at upper right. Photo: D.B. Townsend, GNS Science.

Figure 7 Ice-sculpted glacier cirque basins developed on granitic bedrock in the Hohonu Range, northern Westland. Photo: D.L. Homer, GNS Science CN10184/24.

In the ranges of central to eastern Marlborough, scattered cirque-like features near the crests of the highest peaks suggest local ice cover during glaciations. Cirque-like and moraine-like features are best developed in the Inland Kaikoura Range, where peak heights range from about 1800 m to a maximum of 2885 m at Tapuae-o-Uenuku (Bacon et al., 2001; Figure 5).

The Southern Alps

The Southern Alps run from southeast Nelson southwest to the Hollyford valley, at the northern margin of Fiordland (Figure 4). Along the axis of the Southern Alps is the Main Divide, which defines the boundary between westward- and eastward-draining catchments. Today, glaciers are confined to

the vicinity of higher parts of the Southern Alps, where many peaks exceed 2000 m. The largest modern glaciers occur near Aoraki/Mt Cook (3754 m; [Figure 5](#)).

During late Pleistocene glaciations, ice formed on the Southern Alps, with glacier tongues draining to the northwest and southeast off the mountain chain ([Figure 5](#)). Many of the northwest-flowing glaciers extended out into the lowlands of Westland, producing well-defined glacier troughs rimmed by belts of moraine. In contrast, many of the southeast-flowing glaciers terminated within mountain valleys or basins floored by hard bedrock and, as a result, glacier troughs are not so widely developed and moraines are not so extensively preserved ([Barrell et al., 2011](#)). An outstanding exception is the Pukaki glacier system ([Figures 4 and 5](#)), which drained southeast from the highest part of the Southern Alps into a broad inland basin. Very well preserved sets of moraines and associated meltwater outwash plains surround the Pukaki glacier trough ([Figures 8 and 9](#)). The good preservation of these landforms, and the fact that the moraines are very bouldery and therefore well suited to TCN dating methods, has meant that much effort has been directed to dating the Pukaki moraine sequences using ^{10}Be .

Examining the Pukaki glacier system in more detail, the ages of moraines measured by TCN dating using ^{10}Be indicate that the Late Otira Glaciation ended here about 18 300 years ago as the Pukaki glacier began a sustained retreat ([Putnam et al., 2010a; Schaefer et al., 2006](#)). A resurgence of the glacier is recorded by the Birch Hill moraine ([Figure 10](#)), one of the better expressed late-glacial moraines of New Zealand ([McGregor, 1967; Porter, 1975](#)). Formation of this moraine belt culminated approximately 13 000 years ago, based on TCN measurements, followed by rapid recession ([Putnam et al., 2010b](#)). The age of the Birch Hill moraines coincides with the climax of the Antarctic Cold Reversal climatic event recorded in core samples from the Antarctic ice sheet ([Putnam et al., 2010b](#)).

The Pukaki catchment contains several of the largest modern glaciers in New Zealand ([Figure 11](#)), notably the Tasman, Mueller, and Hooker glaciers. Belts of moraines around the terminus of each glacier have been investigated using a variety of dating methods. Attempts have been made to date these moraines using relative indicators of age, such as the sizes of lichens on rocks (lichenometry; [Burrows, 1973; Lowell et al., 2005; Winkler, 2004](#)), thickness of weathering rinds on rocks (weathering-rind dating; [Birkeland, 1982; Chinn, 1981](#)), and rock hardness determined by the Schmidt hammer method ([Winkler, 2005](#)). These methods are hindered by difficulties in calibrating the measurements to a geological clock, and the variations in results have led to much debate ([Gellatly et al., 1988; Winkler and Matthews, 2010](#)). There has also been success in obtaining radiometric dates from these moraine sequences. Deposits within the lateral moraine belts were exposed as the glaciers shrank during the late twentieth century, revealing fossil soils buried in the moraines. These soils provide a prehistoric record of glacier recession and resurgence. Soil formed on the moraines during ice recession, and was subsequently buried by debris during resurgence of the glacier. Dating of the soils using ^{14}C has provided a chronology of glacier fluctuations ([Burrows, 1989; Röthlisberger, 1987](#)). More recently, TCN dating of large boulders on the surface of the moraines using ^{10}Be has added to the picture of advance and retreat of these glaciers ([Schaefer et al., 2009](#)). The outermost preserved Holocene moraines of the Tasman and Mueller glaciers are about 6000 years old, and lie only about 0.8 km beyond historical ice limits (in New Zealand the historical period begins about 1860 A.D.). As these glaciers were respectively about 28.5 and 13.7 km long when they were at their historical maxima, this means that these glaciers have been no more than between 3% and 6 % longer during the last 6000 years. Thus, the picture that is emerging for the modern glaciers of the Pukaki catchment is that during the last 6000 years, the glacier termini have fluctuated back and forth in about their present locations.

Figure 8 Moraines and meltwater outwash channels on the eastern (true left) margin of the Pukaki glacier trough. Compare to the geomorphological map in [Figure 9](#). Note the distinctively subdued form of the 'Balmoral' (Early Otiran) moraines to the right, compared to the more sharply expressed 'Mt John' (Late Otiran) moraines and outwash terraces in the center. The rather featureless belt of 'Tekapo' moraine close to the lake represents the final advance of the Last Glaciation and subsequent glacier melt-back that began about 18 300 years ago ([Putnam et al., 2010a](#)). Photo: G.H. Denton.

Figure 9 Geomorphology map of the lower reaches of the Lake Pukaki basin, which is an ice-age glacier trough. The map is generated from a Geographic Information System geomorphological map dataset produced for the central part of the South Island (Barrell et al., 2011). The map was compiled for presentation at a scale of 1:100 000, so many details of the landforms are simplified in order to be legible at that scale. A feature of this map is the detailed depiction of landforms, such as ridges of glacier moraine and the locations of river-cut terrace edges. These are factual observations whereas the colors on the map depict an interpretation of the ages of the landforms. The hypotheses that are represented by the coloring on the map can be tested by applying dating methods to the moraines.

Fiordland

The Fiordland massif forms the southwestern corner of the South Island. It is for the most part formed in hard crystalline plutonic and gneissic rocks, and is deeply dissected by steep-sided u-shaped valleys headed by innumerable cirques, with an array of lakes and fiords around the margins of the massif. The massif is highest towards its northern end, with many peaks taller than 1800 m, and numerous present-day cirque glaciers (Augustinus, 1992). On its western (seaward) side, the massif has no coastal lowland and the seafloor descends steeply down the continental slope. In contrast, to the south offshore is a broad continental shelf, and to the east are piedmont basins and valleys (Figure 4).

It is likely that ice on Fiordland approximated a cap during the maxima of the Otira Glaciation (Figure 5). To the west,

many of the outlet glaciers would have reached the sea at the times of glacial maxima/sea level minima, with glacier trough morphologies and submarine outwash fan features evident in fiord and continental slope bathymetries (Barnes, 2009). To the south and east, the glaciers terminated on land. Many of the Late Otiran glacier troughs are occupied by lakes, bordered by moraine and outwash sequences (Figure 12). In places on the south coast, these moraine and outwash sequences are intersected by uplifted coastal terraces (Turnbull et al., 2010).

Little is known of late-glacial or Holocene ice limits because relatively few moraines are preserved in the mid- to upper parts of the catchments. For the most part, the late Pleistocene glacial landforms of Fiordland are dominated by ice-sculpted bedrock topography (Figure 12).

Figure 10 On the lowest flanks of the northeast side of the Tasman River valley, lateral ridges of the Birch Hill moraine (lower right) lie about 500 m below the Late Otiran moraines (center right). The Birch Hill moraines are about 13000 ± 300 years old (Putnam et al., 2010b). Photo: B.G. Andersen.

Figure 11 The Tasman Glacier is New Zealand's longest glacier, its lower reaches covered in a veneer of rock debris. The glacier shrank in height through the early to middle parts of the twentieth century, and Tasman Lake began to form in the late 1970s. Intricately braided outwash plains emanate from the moraine complex. Light-colored outwash areas

Southeastern ranges of the South Island

Several of the highest mountain ranges to the east of the Southern Alps carry geomorphological indicators of former ice cover. These include southeast-facing cirques and cirque-like basins (Figure 13), and over-widened, in some cases u-shaped, upper reaches of main valleys in the ranges. In most cases, it is likely that any such ice-related features were last occupied during the Late Otira Glaciation, though undoubtedly most of these features were initiated during earlier glaciations (e.g., Brook et al., 2008). Notable examples can be seen in the Torlesse Range ($43^{\circ}15'S$), southern Two Thumb Range ($43^{\circ}50'S$), Benmore Range ($44^{\circ}25'S$), Hawkdun Range ($44^{\circ}45'S$), Garvie Mountains ($45^{\circ}30'S$), and Takitimu Mountains ($45^{\circ}42'S$).

Stewart Island

Stewart Island rises from a shallow area of the continental shelf and would have comprised hills surrounded by a coastal plain at times of lower sea levels. No glaciers exist today, but small cirques lie on the southeast sides of two of the highest peaks. Mt Anglem ($46^{\circ}45'S$; ~ 980 m) has two cirques, each containing a small pond impounded by moraine (Allibone and Wilson, 1997). Assigned a Holocene age by Turnbull and Allibone (2003), a Late Otiran age seems more likely, judging by a lack of well-preserved moraines farther downslope. At Mt Allen ($47^{\circ}05'S$; 750 m), a well-defined ridge on its southeast face is thought to be a moraine (Allibone and Wilson, 1997; Brook, 2009b), and is probably of Late Otiran age.

have been part of the active Tasman River floodplain within historic time (since the late 1800s). At center left the Blue Lakes are enclosed within vegetated moraine ridges that range in age from about 900 years (inner ridges) to 1800 years (outer ridges) (Schaefer et al., 2009). Photo: D.L. Homer, GNS Science CN22243, taken April 1992.

Figure 12 A view from the rugged mountains of Fiordland southeast across the Manapouri glacial trough. The lake is studded with islands of ice-shorn bedrock and enclosed by Late Otiran moraines and outwash middle left to right. Photo: D.L. Homer, GNS Science CN10405/5.

Figure 13 Cirque basins at the crest of the Hawkdun Range, North Otago, eastern South Island. These basins have been scooped out by the action of ice during glaciations. The well-defined morphology of the basin floors suggests that glaciers were last active here during the Late Otira Glaciation. Photo: D.L. Homer, GNS Science CN42857/16.

Sub-Antarctic Islands

The largest sub-Antarctic islands of the SW Pacific region are the Auckland Islands, Campbell Island and Macquarie Island. Administratively, the first two are territories of New Zealand, while Macquarie Island is an Australian territory. There is no resident human population on these islands, but the respective governments maintain bases on these islands for purposes that include conservation work and scientific research.

The Auckland Islands ($50^{\circ}50'S$), about 626 km^2 in extent, are the deeply eroded remnants of an Oligocene–Miocene basalt

shield volcano. Many hills rise to between 400 and 600 m above sea level and the highest point is Mt Dick at 705 m. Mean annual temperature near sea level is between 7.5° and 8.1° (McGlone, 2002). The island has abundant evidence of past glacial activity in the form of u-shaped valleys, hanging valleys, moraine-dammed lakes, and cirques (McGlone, 2002). The full extents of ice have yet to be established. There remains the question of whether some of these ice-shaped landforms may have originated during middle Pleistocene glaciations.

Campbell Island/Motu Ihupuku, as it is officially named, lies at $52^{\circ}32'S$ and is the eroded remains of a Miocene volcano.

The island is 113 sq km² in area. Several peaks rise to between 400 and 500 m, with Mt Honey marking the island's highest point at about 570 m. Close to sea level, mean annual temperature is 6.8° (McGlone, 2002). The island has extensive smoothed slopes and broad-floored valleys, the lower reaches of which are now coastal inlets. The landscape has hallmarks of having been shaped by glaciers, although this interpretation has been a subject of debate amongst previous researchers (McGlone, 2002).

Macquarie Island (54°40'S) is long and thin, aligned north-south on the emergent crest of the submarine Macquarie Ridge, and is 129 sq km² in area. Geologically, it is a recently uplifted slice of ocean floor rocks, lying along the Australia-Pacific plate boundary. The island would have been much longer to the north and south, but not much wider, under lowered sea levels during glaciations. Macquarie Island has an irregular plateau-like top, between 200 and 300 m above sea level. Holocene raised beaches around much of the coast of the island indicate continuing uplift. It is not known when the island rose sufficiently high to be emergent above interglacial sea levels, such as today. It is not inconceivable that the island as we see it today is entirely a late Pleistocene feature. The setting of the island, in the Southern Ocean to the south of the Sub-Antarctic Front, results in a cold climate, with mean annual temperature of 4.8°. Opinions have varied on the past extent of glaciations. As summarized by McGlone (2002), earlier workers favored ice cover to some extent on the island, while later workers have favored little or no development of glaciers. The debate revolves around the interpretation of landforms, as to whether their origin is glacial or due to other processes, and is yet to be resolved.

Discussion

The highest mountains of New Zealand intersect the modern snowline, resulting in glaciers that survive in the present-day interglacial climate. During cold episodes during the late Pleistocene, notably in the Last Glaciation, snowlines dropped sufficiently low to allow glaciers to form on many mountainous areas of New Zealand, Tasmania, and the highest part of the Snowy Mountains in southeast Australia. Glaciers are responsive indicators of climatic conditions that leave distinctive landforms marking their former extents. The ability to determine the sizes that glaciers extended to in the past, and to measure when they were that large by geological dating methods, provides a valuable record of prehistoric climate change. In some respects the records of glacier activity from tectonically stable continental areas such as Tasmania and the Snowy Mountains are particularly valuable because there is greater certainty about the height and form of the mountain catchments of those glaciers, over long time periods. By contrast, in tectonically and volcanically active areas such as New Zealand, ongoing uplift of mountain ranges, or the episodic destruction and rebuilding of volcanoes, are complicating factors in the climatic interpretation of glacier landforms.

The development of high-precision TCN dating is a real break-through in the quest to obtain detailed climate change histories from glacier landforms. Much remains to be learned about the detail of prehistoric glacier variations in New

Zealand and Tasmania, and in so doing gaining a better understanding of the climate systems in the SW Pacific region.

Glossary

Cenozoic era: The most recent of the four major subdivisions of geologic time based on the history of animal evolution. The other three are the Proterozoic, Paleozoic, and Mesozoic. The Cenozoic spans about 65 My, from the end of the Cretaceous period to the present.

Deglaciation: This term describes ice retreat. An area is said to have deglaciated when it becomes ice free.

EAIS: Acronym for the East Antarctic Ice Sheet, or the part of the Antarctic glacial system that is east of the Transantarctic Mountains.

Eocene epoch: The Eocene epoch is part of the Tertiary period in the Cenozoic era, and lasted from about 55 to 34 Ma.

Glacial–interglacial: The term ‘glacial’ or ‘glaciation’ refers to a period of colder climate and extended glaciers compared to the present, and conversely ‘interglacial’ or ‘interglaciation’ refers to a period characterized by climate and glacial expansion similar to the present.

Grounding line: The grounding line of a glacier/ice sheet entering the sea describes the position where the ice loses contact with the sea bed and starts to float. Inside the grounding line, subglacial deposition or erosion takes place; outside it, marine and meltwater processes control sedimentation.

Holocene: The term Holocene refers to the present geological time, the past 10 ka since the end of the Pleistocene.

Last Glacial Maximum (LGM): This term refers to the time of global maximum extent of ice sheets during the last glaciation, some 20–18 ka.

Little Ice Age (LIA): A period of cooling and advancing glaciers, lasting approximately from the fourteenth to the late nineteenth centuries.

Marine oxygen-isotope stage (MIS): Oxygen-isotope ratios ($^{18}\text{O}/^{16}\text{O}$) measured in shells of marine microfossils are the basis for recognizing oxygen-isotope stages. The last 900 ka are divided into 23 stages, where even-numbered stages indicate glacial conditions (high $\delta^{18}\text{O}$); odd stages represent interglacial periods (low $\delta^{18}\text{O}$). The present interglacial

period, the Holocene, is numbered MIS-1, and the LGM occurred during MIS-2. Marine oxygen-isotope stages have become a global standard for interpreting Quaternary paleoclimate and chronology.

Marine $\delta^{18}\text{O}$ record: There are three isotopes of oxygen: ^{18}O , ^{17}O , and ^{16}O . The marine $\delta^{18}\text{O}$ record describes the relative abundance of the heavy ^{18}O isotope through time. It increases during glacial periods, when more of the lighter ^{16}O isotope is captured in glacial ice on land.

Miocene epoch: The Miocene epoch is a part of the Tertiary period in the Cenozoic era. It lasted from about 24 to 5.3 Ma.

Neoglaciation: This is a ‘Northern Hemisphere’ term, originally describing a Stone Age cooling occurring after the Holocene climatic optimum, later than 3–2.5 ka BP. Here it is used in a more general sense, meaning late Holocene cooling and growing glaciers.

Oligocene epoch: The Oligocene epoch is part of the Tertiary period in the Cenozoic era, and lasted from about 34 to 24 Ma.

Pleistocene epoch: The Pleistocene epoch covers the bulk of the Quaternary period, between 1.8 Ma and 10 ka.

Pliocene epoch: The Pliocene epoch is the last part of the Tertiary Period, and lasted from about 5.3 to 1.8 Ma.

Quaternary period: The Quaternary period covers the span of time from 1.8 Ma to the present day. It is subdivided into the Pleistocene and Holocene epochs.

Stratigraphic data: The term ‘stratigraphic data’ refers to any geological data that are retrieved from stratified deposits, that is, have bearings on spatial and temporal arrangements of rocks.

Tertiary period: The Tertiary period of geological time spans most of the Cenozoic era, between 65 and 1.8 Ma. It is divided into five epochs: Paleocene, Eocene, Oligocene, Miocene, and Pliocene. In the geological time column, the Tertiary follows the Cretaceous period, and is succeeded by the Quaternary period.

WAIS: This is an acronym for the West Antarctic Ice Sheet, or the huge glacial system that occurs west of the Transantarctic Mountains.

Introduction

Glaciers and ice sheets have existed intermittently in Antarctica for more than 30 My. The Antarctic glacial system can be divided into three main components (Figure 1):

- *The East Antarctic Ice Sheet (EAIS).* It is predominantly terrestrial, relatively stable, and has limited discharge to surrounding ice shelves.
- *The West Antarctic Ice Sheet (WAIS).* It is largely marine based, very dynamic, and discharges huge volumes of ice to floating ice shelves through large ice-stream systems.

- *Ice caps and glaciers on the Antarctic Peninsula.* This system is very dynamic and discharges ice to a number of small ice shelves.

The overall volume of glacial ice in Antarctica is estimated to be about 25 million km^3 , potentially containing 57 m of sea-level equivalent (Lythe et al., 2001). The Antarctic glacial system is an important factor in regulating, modifying, and forcing the global climate and oceanographic system. For the past >30 My, it has driven global sea-level stands and deep-ocean circulation, and acted as a regulator of global climate. Large-scale glaciations in Antarctica are not restricted to the

Figure 1 Map of Antarctica, with sites mentioned in the text.

Quaternary period, and for appreciating the late Quaternary glacial history, some understanding of the Cenozoic development of the Antarctic Ice Sheet is necessary. This review first presents a brief summary of the pre-Quaternary history, and then proceeds with a general overview of the Pleistocene record before relating more detailed reviews of the late Quaternary glacial development.

Pre-Quaternary Glacial History of Antarctica

The following review is a summary of overviews by Denton et al. (1991), Wilson (1995), Anderson (1999) and Hambrey et al. (2002).

Onset of Antarctic Glaciation

The initiation of cooling and glaciation in Antarctica was a consequence of plate-tectonic poleward drift and the isolation of Antarctica due to development of ocean passages and currents around the continent. Increases in deep-sea $\delta^{18}\text{O}$ concentrations show global cooling during the Eocene and Oligocene epochs, and there is compelling evidence (seismic profiles

and glacial diamictons in sediment cores) for an ice sheet on East Antarctica at the Eocene–Oligocene transition (34 Ma). Ice spread into the western Ross Sea by the late Oligocene. Stepwise increase in deep-sea $\delta^{18}\text{O}$ concentrations during the Miocene and into the Pliocene, and stratigraphical data (marine sediment cores, seismic records, and terrestrial sequences) provide evidence for significant middle-to-late Miocene ice-sheet expansion in Antarctica. It has been suggested that the ice sheet over East Antarctica developed into a major and permanent feature about 15 Ma. The data suggest repeated shifts from temperate to subpolar or polar climates throughout the Miocene and expansion of glaciers from the Transantarctic Mountains toward and beyond the Victoria Land coastline. Large ice caps existed on the Antarctic Peninsula, with ice expanded over the continental shelf areas by middle–late Miocene.

Pliocene and the Transition to the Pleistocene

The deep-sea record from around Antarctica suggests significant Pliocene sea-surface temperature fluctuations, and global oxygen-isotope records indicate considerable sea- and ice-volume fluctuations. As Northern Hemisphere ice sheets

were not developed at this stage, it is thought that global sea-level changes were driven by oscillations in Antarctic ice volumes. Seismic records from the Ross Sea region and Antarctic Peninsula continental shelf show a number of shelfwide unconformities bounding till sheets, indicating waxing and waning of continental glaciers during the Pliocene. Sediment cores from the western Ross Sea have meltwater deposits interbedded with till sheets, signifying repeated glacier oscillations in the Victoria Land region.

The Pliocene terrestrial record of Antarctic glaciations is fragmentary and difficult to interpret, and different opinions exist as to the Miocene–Pliocene stability of the EAIS. Reconstructions range from drastic fluctuations, with the ice sheet oscillating between extensive collapse and very extensive buildup and mountain overriding, to suggestions that it has existed close to its present configuration for the past ~14 My (Barrett, 1997; Denton et al., 1993). The greatest controversy focuses around different interpretations of the fossil evidence from the so-called Sirius Group. It has not been resolved whether the ice sheet underwent sufficient massive changes in ice volumes to allow the interior East Antarctica to become ice free, alternating with very extensive glacial overriding of the Transantarctic Mountains (Anderson, 1999; Barrett, 1997; Denton et al., 1991; Wilson, 1995). The Pliocene history of the WAIS is scantily known, but seismic records from the Antarctic Peninsula continental shelf indicate that there were repeated fluctuations in ice volume during the Pliocene (Anderson, 1999). The combined evidence suggests that ice sheets advanced to the edge of the continental shelf around Antarctica during the late Pliocene, with an ice extent similar to or greater than during the Last Glacial Maximum (LGM), and that those glaciations were interrupted by interglacial episodes that may have been warmer than the present.

Pleistocene Glacial Cycles in Antarctica

The Pleistocene record of glacial events in Antarctica is fragmentary due to the lack of long Pleistocene sediment sequences (marine core or sections on land) with good time resolutions. Stratigraphic data from sites in the Transantarctic Mountains record a major cooling in the early Pleistocene, and that the EAIS overrode the mountains during several episodes of extensive Pleistocene glaciations. The West Antarctic continental record is similarly fragmentary, but available data suggest that the WAIS was considerably thicker than at present on several occasions during the early and middle Pleistocene, and probably grounded on the shelf edge. Seismic profiles and core data from many shelf area locations off Antarctica show numerous stacked till sheets interbedded with glaciomarine and meltwater sediments. The controlling mechanisms for waxing and waning of the Antarctic Ice Sheets are not well understood. Hollin (1962) concluded that there is an overall in-phase relationship between glacial cycles in the Northern and Southern hemispheres, perhaps driven by falling and rising global sea levels regulated by buildup and decay of Northern Hemisphere ice sheets.

The Pleistocene stability of the marine-based WAIS has been discussed since Mercer (1968) suggested that it had repeatedly collapsed during Pleistocene interglacials. A model

study by MacAyeal (1992) showed that sporadic collapse of the ice sheet occurred throughout the past 1 My, and data have been presented (Scherer et al., 1998) that suggest that the WAIS collapsed at least once during the late Pleistocene. This remains to be tested through long sedimentary sequences highlighting the structure and timing of interglacial and glacial cycles. The deep-sea $\delta^{18}\text{O}$ record suggests that during the last interglacial (130–115 ka BP) there was less global ice volume than at present. It has been suggested that the collapse of the WAIS caused global sea levels to be 5–6 m higher than present during isotope stage 5e. If this episode of high global sea-level stand signifies collapse or decay of the WAIS (Mercer, 1968), if the water source was the Greenland Inland Ice (Cuffey and Marshall, 2000), or if it came from melting of the Northern Hemisphere ice sheets and partial melting of the Antarctic Ice Sheet (Denton et al., 1971) are issues that remain unresolved.

The available data indicate that the Antarctic glacial system has evolved through time: during early periods (Oligocene–Miocene), it was largely temperate in the coastal areas. A transition to cooler conditions followed in the Pliocene, and during much of the Quaternary it has been a stable, cold system.

Last Glacial Cycle and the LGM in Antarctica

Studies on late Quaternary glacial and climate changes in Antarctica have relied heavily on ice-core records (EPICA community members, 2004; Petit et al., 1999) and marine records (Anderson, 1999; Anderson et al., 2002; Bentley and Anderson, 1998). The evidence from ice-free areas in Antarctica is primarily based on stratigraphic and morphologic investigations, studies of lake sediment and moss-bank cores, and of fossil penguin rookeries (Berkman et al., 1998; Ingólfsson et al., 1998). While Antarctic ice cores depict glacial cycles in the form of oxygen-isotope and atmospheric compositions for the past ~800 ka (EPICA community members, 2004), this information is not easily translated into glacial history. There are large discrepancies between reconstructions of Antarctic late Quaternary glacial and climate history based on the geological data and ice-core records (Ingólfsson et al., 1998, 2003; Masson et al., 2000). The following summary focuses on the terrestrial and offshore geological records as the most reliable proxies for the glacial history of Antarctica. All ^{14}C ages are given in the text as uncalibrated ^{14}C years BP, reported as ka BP. The review relies on previous overviews by Denton et al. (1991), Bentley and Anderson (1998), Berkman et al. (1998), Ingólfsson et al. (1998), Anderson (1999), and Anderson et al. (2002).

Little is known about the extent of glaciation prior to the LGM during the last glacial cycle. Bentley and Anderson (1998) suggested that ice volumes in the Antarctic Peninsula region were considerably greater before 35 ka BP than at the 20–18 ka BP LGM. Hjort et al. (2003) suggested that ice cover during the earlier part of the last glacial cycle was more extensive than during the LGM. That earlier glaciation was followed by an interstadial, probably during marine oxygen isotope stage 3 (MIS 3), and thereafter by the LGM glaciation. There are a number of coastal sites around Antarctica where fossil-bearing pre-LGM marine interstadial or interglacial sediments occur (Berkman et al., 1998). A number of radiocarbon dates from a few sites constrain a possible interstadial between 30 and

Figure 2 Extent of ice over Antarctica at the Last Glacial Maximum (LGM) and constraining minimum ages for ice retreat and deglaciation. Radiocarbon dates are given as ka BP. Data compiled from [Anderson et al. \(2002\)](#) and [Ingólfsson \(2004\)](#).

45 ka BP, but the sites are too few and too poorly constrained to draw conclusions as to the pre-LGM fluctuation pattern of the Antarctic Ice Sheets.

Most models suggest that during the LGM, the ice was considerably thicker and more extensive than present (see [Figure 2](#)). There are data showing that some coastal areas remained wholly or partly ice free, and there were numerous nunataks protruding above the ice surface in coastal and inland mountain ranges. LGM ice extended at least onto the mid-shelf areas off the western Antarctic Peninsula, the Weddell Sea, and East Antarctica, whereas it probably grounded close to the continental shelf edge off the Ross Sea. The timing of the last maximum glacial expansion around Antarctica is poorly constrained by ^{14}C dates, but most authors assume it to have coincided with the timing of lowest global sea levels during MIS 2, around 20–18 ka BP.

Deglaciation and Holocene Development of Glaciation and Climate in the Antarctic Peninsula Region

Deglaciation of the Shelf and Near-Shore Areas

The oldest ^{14}C dates, constraining ice retreat from the outer and middle shelf areas west of the Antarctic Peninsula, come from the Bransfield Strait and the shelf areas west of Anvers Island. These indicate ice retreat by 14–13 and 12–11 ka BP, respectively. The Palmer Deep area was ice free around 11 ka BP. Most dates from the inner shelf areas and fjords and bays on the peninsula constrain deglaciation to as late as 8–6 ka BP. Glaciomarine sedimentation in the central part of the Gerlache Strait began after 8 ka BP, providing a constraining

minimum date for deglaciation and shelf-ice retreat in the strait. Similarly, the onset of glaciomarine sedimentation in Lalleman Fjord occurred ca. 8 ka BP. The inner shelf areas around Anvers Island and in Marguerite Bay were ice free at 7–6 ka BP.

Deglaciation of Presently Ice-Free Coastal Areas

The deglaciation of coastal areas that are presently ice free is constrained by the minimum ages obtained from ^{14}C -dating of subfossil mollusk shells from raised marine deposits, peat deposits in moss-banks on the islands off the Antarctic Peninsula, organics from lake sediments, and remains from abandoned penguin colonies (see [Figure 3](#)). The oldest ^{14}C dates give minimum ages for deglaciation on the South Shetland Islands as 9–8 ka BP. Northern James Ross Island deglaciated prior to ca. 7.4 ka BP. In the south, George VI Sound became free of shelf ice 6.5–5.7 ka BP. Data from fossil penguin rookeries in Marguerite Bay suggest initial colonization in the period 6.5–5.5 ka BP ([Emslie, 2001](#)), which confirms minimum ages for deglaciation of 7–6 ka BP provided by marine-geological studies. The marine limit, which regionally lies between 30 and 55 m a.s.l., dates to ca. 7 ka BP and conforms with relatively late coastal deglaciation.

Once the glaciers were inside the present coastline, glacial retreat and ice disintegration was slow. On King George Island, glaciers were at or within their present limits by ca. 6 ka BP, and on northern James Ross Island prior to 4.7 ka BP, but parts of Livingston Island deglaciated as late as 5–3 ka BP. A minimum date for deglaciation on Elephant Island is provided by the onset of moss-bank formation on the steep slopes by 5.5 ka

Figure 3 A pair of Gentoo penguins nesting on the Antarctic Peninsula. The earliest Holocene penguin occupation in the Antarctic Peninsula region dates back to ~6.5 ka BP, which is an indication of relatively late deglaciation. Photo by Ó. Ingólfsson, 1987.

BP. There are indications from a number of sites that glaciers readvanced during the period <6–4 ka BP (Ingólfsson et al., 2003). Advances have been described from King George Island (5–4 ka BP), Brabant Island (later than 5.3 ka BP), James Ross Island (around 4.6 ka BP), and Hope Bay (around 4.7 ka BP). It is also known that the George VI Sound ice shelf expanded after 5.7 ka BP.

Holocene Climatic Optimum

Björck et al. (1996) presented a paleoclimatic synthesis for the Holocene development in the Antarctic Peninsula region, based on a compilation of numerous stratigraphic variables in lake sediments and moss-bank peat. Their reconstruction indicates that a regional warming began around 4.2 ka BP and reached an optimum around 3 ka BP, followed by a distinct and rapid climatic deterioration. A marine record from Lallemand Fjord recognizes a climatic optimum, reflected by high productivity and minimal sea ice in the fjord, between 4.2 and 2.7 ka BP.

Neoglaciation 3–0.1 ka: Cooling, Expanding Glaciers, and Increased Sea Ice

Since 3 ka BP, the climate has fluctuated between cold-dry and cool-humid, but remaining colder compared to the situation during the climatic optimum. Glaciers have oscillated and expanded somewhat in the Antarctic Peninsula region during the past ~2.5 ka, and glacial advances on the South Shetland Islands have been correlated to the Little Ice Age (LIA) expansion of glaciers in the Northern Hemisphere. The marine records suggest cooling expressed as decreased fjord/near-shore biologic productivity and more extensive and seasonally persistent sea ice after 3 ka BP.

The Last 50 Years: A Distinct Warming

The western Antarctic Peninsula region has moved to an increasingly warm climate regime during the past 50 years (Smith et al., 1999). Ecosystem research indicates that ecological transitions have occurred in response to this climate

change. A number of the Antarctic Peninsula ice shelves have been retreating with increasing speed since the late 1980s.

Deglaciation and Holocene Development of Glaciation and Climate in East Antarctica

Data highlighting the dynamics and patterns of deglaciation along the vast East Antarctic coastline, from the Weddell Sea to the Ross Sea, is extremely sparse. Ice-free areas in East Antarctica are few and far in between, and there is a lack of well-constrained marine records. This review relies on previous overviews by Denton et al. (1991), Berkman et al. (1998), Ingólfsson et al. (1998), Anderson (1999), and Anderson et al. (2002).

Queen Maud Land

There are very few constraints on the deglaciation in the eastern sector of the Weddell Sea and Queen Maud Land. Grounding line retreat in the Weddell Sea was underway about 13 ka BP. Post-LGM lowering of the ice-sheet profile at Vestfjella and Heimefrontfjella has been estimated to 700 and 200 m, respectively. The oldest avian occupation (proxy for deglaciation) there has been dated to 7.4 ka BP, but details as to glacial and climate fluctuations are lacking. Grounding line retreat on the Lazarev Sea shelf was underway prior to 9.5 ka BP, but reliable deglaciation chronologies for the Schirmacher and Untersee oases are lacking.

MacRobertson Land, Amery Oasis, and Amery Ice Shelf

Data from marine cores off MacRobertson Land suggest that deglaciation of the outer shelf occurred prior to 10.8–10 ka BP. The Amery oasis deglaciated prior to 12.7 ka BP, signifying an ice-surface lowering of the Lambert Glacier. A study of lake sediments revealed two postglacial periods of relatively warm conditions: an early period peaking around 7.8 ka BP and a later peaking around 3 ka BP (Wagner et al., 2004). The large Amery Ice Shelf has been present throughout the Holocene.

Larsemann Hills and Vestfold Hills

A number of radiocarbon dates from sediment cores in the Larsemann Hills give mid-Holocene ages for the deglaciation of the oasis. The last deglaciation of the Vestfold Hills has been determined by ^{14}C dates on mollusks from raised marine deposits and moraines, on marine algal sediments from numerous lake basins, and on fossil mosses. The oldest ^{14}C dates, giving minimum ages for the initial deglaciation and the incursion of marine water onto coastal areas, as well as for the initiation of aquatic moss growth, are between 8.6 and 8.4 ka BP. Relative sea level stood at the marine limit in the Vestfold Hills at ~9 m a.s.l., at ca. 6 ka BP. A number of studies indicate that a climate optimum can be recognized between ca. 4.7 and 2.5 ka BP. A late Holocene glacial expansion (the Chelnok glaciation) occurred between 2.5 and 1 ka BP. There is evidence for minor late Holocene (post 0.7 ka BP) ice marginal advances, in the form of a discontinuous series of ice-cored moraine ridges, which may be an LIA event. A study of marine

sediment cores from the Vestfold Hills area recognizes a significant cooling and increase in sea-ice cover after 2.5 ka BP.

Bunger Hills

Numerous ^{14}C dates indicate that the initial deglaciation of the Bunger Hills oasis dates back to between 10 and 8 ka BP. The glacial retreat was partly controlled by the rise of sea level, which caused a relatively rapid collapse of the ice-sheet margin. Breeding colonies of snow petrels expanded continuously following ice retreat and downwasting of dead ice, with the most intense phases of colonization between 6.7 and 4.7 ka BP. Before 5.6 ka BP, when the sea stood at the marine limit at between 9 and 7 m, glaciers were at or behind their present margins. A glacier advance, forming moraines called the Older Edisto Moraines, is bracketed between 6.2 and 4.7 ka BP. A high and stepwise increasing biogenic production in lakes between 3.5 and 2.5 ka BP has been taken to indicate increased temperatures and a climate optimum. It was followed by an abrupt and dramatic cooling that took place within less than 200 years. The so-called Younger Edisto Moraines postdate 1.1 ka BP and have been suggested to be an LIA glacial event.

Windmill Islands

The Windmill Islands deglaciated prior to 8 ka BP. A recent study by Roberts et al. (2004) found indications of a climate optimum in mid-Holocene. There is evidence for a readvance of the Law Dome ice-sheet margin onto part of the Windmill Islands some time between 4 and 1 ka BP. The readvance has been attributed to a positive mass balance on the Law Dome caused by high-precipitation rates during the Holocene.

Deglaciation and Holocene Environmental Development in Ross Sea and Victoria Land

This review relies on previous overviews by Denton et al. (1991), Berkman et al. (1998), Ingólfsson et al. (1998), Anderson (1999), Conway et al. (1999), Hall and Denton (2000), and Anderson et al. (2002).

Deglaciation and Grounding Line Retreat

A number of ^{14}C dates constrain the marine-based ice-sheet retreat in the Ross Sea from the LGM grounding line after 17 ka BP. The minimum age for grounding line retreat south of Terra Nova Bay is ca. 11.4 ka BP. The breakup of the shelf ice was probably considerably delayed. The minimum age for the deglaciation of coastal Terra Nova Bay is some time before 6.2 ka BP, when the coasts there became free of ice and marine habitats could begin to develop. The oldest penguin rookeries in Terra Nova Bay date to 5.8 ka BP.

Dating of penguin rookeries on Ross Island and in the McMurdo Sound area give minimum ages for the deglaciation in the southern Ross Sea, being 6.8–5.7 ka BP, and marine fossils collected from debris bands on the McMurdo Ice Shelf date the grounding line recession of the Ross Sea Ice Sheet to a position south of Black Island by 6.3 ka BP. ^{14}C dates on fossil marine mollusks from raised beaches along the southern Victoria Land coast, McMurdo Sound, and the islands in the

southwestern Ross Sea, as well as additional dates on penguin occupation in McMurdo Sound, all give minimum ages for the deglaciation as ca. 6.3–6.1 ka BP. A relative sea-level curve for the southern Victoria Land coast indicates unloading of grounded ice by 6.5 ka BP and provides one minimum estimate for the deglaciation (Hall and Denton, 1999).

Mid-late Holocene Glacier Oscillations

After the deglaciation in Terra Nova Bay, the ice shelves entering the bay were less extensive than today. The ice margins stood 2–5 km inside their present margins between 6.2 and 5.3 ka BP, but readvanced some time after 5.3 ka BP. After a withdrawal, moraine ridges containing fossil marine shells show a glacial readvance in Terra Nova Bay after 0.5 ka BP, which has been interpreted to correspond to the LIA glacial expansion in the Northern Hemisphere. The Wilson Piedmont glacier retreated inside the coast between 5.7 and 5 ka BP, but readvanced in late Holocene times, and at a number of locations it advanced across raised beaches that date back to 5.4–5 ka BP.

Climatic Optimum in Victoria Land

The best information on environmental development in Victoria Land during the later part of the Holocene comes from the spatial and temporal distribution of penguin rookeries (Baroni and Orombelli, 1994). They documented continuous presence of Adélie penguins after ca. 7 ka BP, but the greatest diffusion of rookeries occurred between 3.6 and 2.6 ka BP. Baroni and Orombelli concluded that this 'penguin optimum' was a period of particularly favorable environmental conditions. It was followed by a sudden decrease in the number of penguin rookeries in southern Victoria Land shortly after 2.6 ka BP, attributed to an increase in the sea ice. Raised beaches formed after 5 ka BP, with rounded cobbles indicating high-wave energy at the time of their formation, have been described from a number of sites in southern Victoria Land (Figure 4). At many of these sites today, the ice foot rarely breaks up and recent beaches are of low-energy type.

Figure 4 Raised beach ridge of middle-late Holocene age in southern Victoria Land. Well-rounded cobbles and boulders suggest high-wave energy at the time of beach-ridge formation. At this site today, the ice foot rarely breaks up and recent beaches are of low-energy type. Photo by Ó. Ingólfsson, 1994.

Figure 5 A broad synthesis of the glacial and environmental history of Antarctica since the LGM.

Summary of the Late Quaternary Glacial History of Antarctica

The following broad pattern describing the late Quaternary glacial history of Antarctica can be recognized (Figure 5):

1. Little is known about late Quaternary interglacials–interstadials older than the LGM. There are indications of deglaciation 30–45 ka BP and subsequent LGM glaciation.
2. LGM glaciers from Antarctica generally grounded on the middle to outer shelf, and ice retreat from the LGM positions was underway by 17–14 ka BP.
3. Deglaciation occurred mainly during the time period >14–6 ka BP. Outer- and middle-shelf areas deglaciated between 14 and 8 ka BP, while most inner shelf areas, fjords, bays, and, most presently, ice-free coastal land areas deglaciated prior to 8–6 ka BP.
4. The transition from glacial to interglacial conditions in Antarctica, characterized by an ice extent similar to or less than at present, the onset of lake-sediment accumulation in ice-free basins, moss-bank growth on the islands off the Antarctic Peninsula, and penguin occupation of coastal rookeries, was broadly completed by 6 ka BP.
5. Mid-Holocene glacial expansion events have been described from a number of sites.
6. A circum-Antarctic Holocene climate optimum occurred in the period 4.5–2.5 ka BP, followed by a distinct cooling. Many outlet glaciers and ice shelves expanded during the

late Holocene, suggesting a possible LIA glacial event in Antarctica.

7. A significant warming has occurred in the Antarctic Peninsula region for the past 50 years.

Eemian Stage Interglacial

The late Pleistocene started with a warm stage, named the Eemian in NW Europe. This article considers only those glaciogenic sediments that obviously postdate the terrestrial or marine Eemian-age formations.

Correlation of the Eemian interglacial Stage *sensu stricto* with the Marine Isotope Stage (MIS) stratigraphy was not perceived as a problem until recently, as it has generally been assumed that boundaries identified using a variety of proxies on land were precisely coeval with those seen in ocean sediments. Yet, the different response rates of different proxies to climate changes and these changes themselves may be time transgressive. Off Portugal, [Shackleton et al. \(2003\)](#) demonstrated that the MIS 6/5 boundary is not coeval with the Saalian/Eemian Stage boundary on land, as previously assumed. There is a gap of 6000 years between the beginning of the Eemian (126 ka), defined on the basis of palynology, and MIS 5e (132 ka), defined on the basis of oxygen isotope determinations from the same sediments. Similar problems may arise at the end of the event. Thus, land and marine sequences must be correlated with considerable caution as it cannot be assumed that the boundaries recognized in different situations are indeed coeval.

While the Eemian has been traditionally correlated with MIS 5e Substage, the Sangamonian of North America is normally equated with all of MIS 5, which includes the early, very warm Weichselian interstadials (Brörup, Odderade) of Europe. It also includes the cold Marine Isotope Substages 5b and 5d, during which, as pointed out later, major ice sheets may have developed. However, some North American scientists use the Sangamonian for only Marine Isotope Substage 5e.

Eemian marine deposits are well known from western Norway, Denmark, northern Germany, Poland, Finland, and along the northern margin of European Russia and Siberia ([Figure 1](#)). The Eemian probably included the last marine transgression into the Baltic Sea basin before the Holocene. The Eemian Sea is traceable around Fennoscandia into the White Sea basin, where it is described as the Boreal Transgression, and farther eastward across the Russian Arctic ([Funder et al., 2002](#)). For a century, the Boreal formation, with its characteristic Atlantic fauna, has been known as a major stratigraphical landmark of northern Russia. In West Siberia and on the Taimyr Peninsula, the Kazantsevo Formation, which includes the extinct mollusk *Cyrtodaria angusta*, was traditionally accepted as its counterpart (e.g., Kind, 1974). However, lately it has been geochronometrically demonstrated that a much younger Karginsky Formation corresponds to the Eemian ([Astakhov and Nazarov, 2010](#)). The greater extent of the Eemian Sea, as compared to that of the Holocene, has been

explained by the major extent and thickness of the Saalian ice sheets and the different deglaciation history of the Saalian and Weichselian ice sheets.

Besides the marine sediments, an important stratigraphic marker separating the deposits of the last glaciation from older strata is provided by terrestrial formations with a high organic content that fill in numerous depressions overlying the middle Pleistocene glaciogenic sequences.

Weichselian Cold Stage

Northern Russia

Originally, on the basis of mapped boulder trains and the occurrence of fresh-looking hummock-and-lake landscapes, the latest ice sheets of the West Siberian and Pechora Lowlands were thought to have been confined to the Arctic and fed from upland ice domes of the Urals, Novaya Zemlya, Putorana Plateau of Central Siberia, and Byrranga Mountains in the Taimyr Peninsula. It was only through the widespread use of remote sensing data in the 1970s that many push moraines were detected, the configuration of which in most places contradicted the mountain glaciation hypothesis and testified to upslope ice flow from the coastal lowlands of the Kara Sea toward the high areas of the Urals and Taimyr. The mapped pattern of ice-pushed ridges could form only if the ice sheet was centered on the Barents and Kara Sea floors. During the most extensive glaciations, the northbound drainage was blocked by the advancing glaciers, forming huge ice-dammed lakes ([Astakhov, 1977, 1998](#)). Apart from ice-marginal features belonging to the vast Kara Ice Sheet, only traces of small alpine glaciers were mapped in the Polar Urals. The late Pleistocene ice sheet was thinner than that during the middle Pleistocene, but was sufficiently thick to push morainic ridges up to 560 a.s.l. on the northern slope of the Urals. This trimline suggests that ice was at least 1 km thick on the Kara shelf.

During an early phase of the last Ice Age, very large morainic loops, overlying interglacial marine sediments, were deposited in the southern part of the Taimyr Peninsula. These morainic assemblages, together with boulder trains, pointed to a former ice divide north of the Byrranga Mountains, that is, in the north eastern Kara Sea region ([Makaveyev et al., 1982](#)).

When it was demonstrated that large ice domes were located on the Kara Sea shelf, the former paleogeographical paradigm changed and totally different ideas of Weichselian ice limits in the Arctic were envisioned. The determination of several finite radiocarbon dates from beneath the youngest till tipped the scale of the discussion toward the idea of a very extensive last glaciation, comparable to the style of the well-studied Late Wisconsinan Laurentide and Late Weichselian

Figure 1 Extent of the Eemian Sea. Reproduced from Ehlers J (2011) *Das Eiszeitalter*, p. 363. Heidelberg: Spektrum.

Fennoscandian glacial systems. Grosswald (1980), the most ardent proponent of the maximalist model, maintained that Weichselian ice sheets in northern Russia ca. 20 ka extended far south of the Arctic Circle, close to the middle Pleistocene ice limit. However, subsequent testing of the maximalist concept in West Siberia and in European Russia has led to the rejection of a Late Weichselian age for non-Scandinavian glaciers. It turned out that finite radiocarbon dates from sediments overlying the uppermost till greatly outnumbered those from beneath the till. The assumption that the Late Weichselian ice sheet was much smaller than the penultimate glaciations was substantiated by radiocarbon dates obtained from frozen mammoth carcasses and other remains demonstrating that these northern areas were not covered by glacier ice after the animals' death 35–40 ^{14}C ka. It is now clear that most of the old conventional ^{14}C dates from beneath the uppermost till are spurious (Astakhov, 1998, 2006; Astakhov and Nazarov, 2010). This is why the last Siberian interglacial and the Kargin'sky marine transgression were previously erroneously correlated with MIS 3 (e.g., Kind, 1974).

During the last decade, studies of the glacial history of the Barents and Kara Sea regions were carried out within the framework of the European Science Foundation programme Quaternary Environments of the Eurasian North (QUEEN) and by several multinational subprojects. Marginal formations of the Weichselian glaciation maximum were mapped using photogeological interpretation and dated by radiocarbon and luminescence methods. This work has established that the first major glacial advance from the Barents and Kara Seas into the

Russian mainland occurred during an early phase of the Weichselian Stage, some 80–100 ka (Svendsen et al., 2004). During this glaciation, a huge ice-dammed lake, named Lake Komi, formed over the Pechora Lowland in the European part of Northern Russia (Mangerud et al., 2004). It is probable that an even larger ice-dammed lake formed over the West Siberian Lowland (Astakhov, 2006). Later, the northern rim of the continent was affected by a younger advance during the period 70–50 ka. It deposited the Markhida moraine north of the Arctic Circle in the Pechora drainage basin (Svendsen et al., 2004). Recent research has also confirmed the absence of sizeable Late Weichselian mountain glaciers in the Urals, on the Taimyr Peninsula, and even in the higher East Siberian mountains (Hjort et al., 2004; Mangerud et al., 2008; Stauch and Gualtieri, 2008).

The main signature of the last ice sheet in the West Siberian Plain is fine-grained diamicton with blocks of frozen sand, laterally replaced by huge flat-lying fields of dead ice 5–60 m thick, which are barely covered by melted-out silts (Figure 2).

The massive ground ice that is normally banded and deformed, sometimes with suspended boulders, is believed to be mostly remnants of the Early to Middle Weichselian basal glacier ice, preserved in the thick Pleistocene permafrost. The number of sites, the degree of their preservation, and probable age increase eastward from the northeastern corner of the European Arctic toward the East Siberian Sea.

This direct signature of former glaciation is instrumental in delineating the Weichselian ice margin in the central lowland between the Ob and Yenisei river valleys. On the Gydan and

Yamal peninsulas, the massive buried ice is overlain in places by cold-water marine silts with *Portlandia arctica*. However, it is very unlikely that buried glacial ice, normally found at low altitudes, could survive the Eemian marine transgression which, judging from the Atlantic fauna, had bottom temperatures well above zero. Thus, the area with known sites of massive buried ice is thought to have been covered by an ice sheet that is younger than the Eemian marine inundation but beyond the range of the radiocarbon method (more than 40 ka) (Astakhov, 1998, 2006).

Figure 2 Late Pleistocene dead glacier ice covered by melted-out silt on the Gydan Peninsula in West Siberia, 70° N/75° E. This banded and deformed ice is a counterpart of Scandinavian basal tills. Photograph by V. Astakhov.

Along the eastern border of the Plain, a hummock-and-lake landscape continues to develop by glaciokarst of stagnant ice bodies. A flat plain at 45–55 m a.s.l., composed of thick glaciolacustrine rhythmities, intrudes into this hummocky terrain of the Yenisei valley close to the Arctic Circle. The rhythmities are overlain by alluvium, radiocarbon dated to 34–42 ka at Farkovo, and by sinkhole silts containing frozen logs with dates from 35 ka to infinite at Igarka (Kind, 1974). Based on comprehensive investigations, it has now been demonstrated that during the Last Glacial Maximum (LGM), a major ice sheet did exist in the Barents Sea–Svalbard region (Landvik et al., 1998), but it did not expand into the Russian mainland. This ice sheet limit is now identified well offshore in the Barents Sea, based on marine cores and seismic data (Svendsen et al., 2004).

No observations indicate that there was an ice-dammed lake along the northern rim of the Russian Lowland during the Late Weichselian, suggesting that northbound drainage was not blocked by a coherent ice sheet (Astakhov, 2006). Accordingly, the glacier advance that reached the NW coast on Taimyr may have been unconnected with the Barents–Kara Ice Sheet, so there may have been an ice-free corridor on the shelf (Mangerud et al., 2002).

Thus, on the basis of modern data, the LGM was preceded by at least two major Weichselian glaciations. The Early Weichselian ice sheet (Figure 3) that went far inland and blocked the major West Siberian rivers was followed by an independent ice advance from the northeast (Figure 4) that did not dam the Yenisei river (Svendsen et al., 2004). Further to the NE, the Middle Weichselian ice limit of the Yenisei region can only be traced by morainic arcs, which block deep valleys dissecting the Putorana Plateau. Traditionally, these moraines, locally

Figure 3 Extent of the Early Weichselian glaciation. Reproduced from Ehlers J, Gibbard PL and Hughes PD (eds.) (2011) *Quaternary Glaciations – Extent and Chronology, Part IV – A Closer Look. Developments in Quaternary Science*, vol. 15. Amsterdam: Elsevier.

Figure 4 Extent of the Middle Weichselian glaciation. Reproduced from Ehlers J, Gibbard PL, and Hughes PD (eds.) (2011) *Quaternary Glaciations – Extent and Chronology, Part IV – A Closer Look. Developments in Quaternary Science*, vol. 15. Amsterdam: Elsevier.

Figure 5 Extent of the Late Weichselian glaciation. Reproduced from Ehlers J, Gibbard PL, and Hughes PD (eds.) (2011) *Quaternary Glaciations – Extent and Chronology, Part IV – A Closer Look. Developments in Quaternary Science*, vol. 15. Amsterdam: Elsevier.

called the Norilsk Stade, were attributed to the Late Weichselian, and even to the Younger Dryas Stadial (Kind, 1974). However, more recent investigations of the bottom sediments of Lake Lama, situated on the proximal side of the Norilsk Moraine, suggest that the lacustrine sedimentation in this

basin began before the LGM (Svendsen et al., 2004). If correct, this may imply that the last coherent ice cap on the Putorana Plateau is older and that the Late Weichselian glaciation was more restricted than suggested by the radiocarbon dates from the submill sediments mentioned above (Figure 5).

In the perennially frozen Russian Arctic, postglacial time began at ca. 50 ka BP when present-day river valleys developed across morainic landscapes and the bottoms of drained proglacial lakes. The valleys provided sufficient vegetation to allow the first Paleolithic hunters to penetrate beyond the Arctic Circle as early as ca. 40 ka BP (Svendsen et al., 2010). Most finds of mammoth fauna belong to this large and cold, basically treeless interstadial ca. 50–25 ka BP called the Byzovaya in European Russia and Varyakha in West Siberia. The LGM time on the Russian arctic mainland is represented by a mantle of loess-like silts with ice wedges, and rare remains of a mammoth fauna (Astakhov and Nazarov, 2010).

Scandinavian Ice Sheet

In contrast to the spectacular changes regarding the Weichselian ice-sheet configuration in northern Russia over the last decade, much less new information is available from the Scandinavian Ice Sheet area (Figure 6). The maximum ice advances of the last cold stage both in Britain and continental Europe did not occur before the last part of the Weichselian (Devensian) Stage. Nevertheless, there can be no doubt that

extensive glaciers existed in northern Europe also during the Early Weichselian substage (Mangerud, 2004). The exact extent of the Early Weichselian glaciations in Scandinavia, the deposits of which have been identified in Norway, Finland, and northern and central Sweden, is so far unknown. It is certain, however, that it was less extensive than the Late Weichselian glaciation. Finnish Lapland has traditionally been considered ice-covered between the Eemian Stage and the Early Weichselian Brørup Interstadial. This is suggested by the fact that deposits of the two periods are always found separated from each other by a till bed (Hirvas, 1991). Recently, it has been shown that this first ice cover (at locality Sokli) was during isotope stage 5b (Helmens et al., 2000). However, farther to the south, in Finland, there is no evidence of Early Weichselian glaciation. Thermoluminescence (TL)- and optically stimulated luminescence (OSL)-dated Early Weichselian buried podsols and overlying sands seem to indicate that central and western Finland remained ice free (Lunkka et al., 2004).

Major ice-sheet expansion in the southern Baltic region induced an ice stream to spread fanlike across Denmark (Houmark-Nielsen, 2010), and eventually glaciers covered most of the country early in the Middle Weichselian MIS 3

Figure 6 The right-hand panel shows a schematic glacialization curve for the southwestern flank of the Scandinavian Ice Sheet through the Weichselian. Reproduced from Mangerud J, Gyllencreutz R, Lohne Ø, and Svendsen JI (2011) Glacial history of Norway. In: Ehlers J, Gibbard PL, and Hughes PD (eds.) *Quaternary Glaciations – Extent and Chronology. Part IV. A Closer Look*. Amsterdam: Elsevier. The curve shows how the glaciers expanded from the mountains, out from the valleys and fjords, and finally onto the continental shelf. Names on the curve represent geological sites. The Laschamp and Mono Lake paleomagnetic excursions are marked with arrows. The curve to the left is a stacked record for grain % of IRD in five cores, and the middle curve a stacked record of accumulation rates in three cores; all cores collected from the Vøring Plateau (Baumann et al., 1995). The time scale is (in principle) in calendar years, but the curves are partly dated and correlated with different methods.

between 55 and 48 ka. For North Germany, [Stephan \(2003\)](#) claims a first Weichselian ice advance around 60 ka BP (Ellund Advance). [Müller \(2004\)](#) even postulates that the early ice advance reached the Weichselian maximum limit (Warnow Phase).

In northern Denmark and southwestern Sweden, deposits of the Kattegat ice lake were overridden by the Kattegat Ice Stream about 30–27 ka. The latter reached its maximum across central Denmark and in northwest Skåne and deposited till of Norwegian provenance ([Houmark-Nielsen, 2003; Larsen et al., 2009](#)), while periglacial conditions with Arctic treeless vegetation were maintained in southern Denmark. Deglaciation caused the Kattegat ice lake to reopen; however, it was still dammed off from the Atlantic Ocean by glacier ice flowing out of the Norwegian Channel ([Houmark-Nielsen, 2011](#)).

In Norway and Sweden, there was a major deglaciation after MIS 4 and much, probably even most, of Scandinavia was ice free during MIS 3 interstadials, especially during the Ålesund Interstadial ([Mangerud et al., 2010; Wohlfarth, 2010](#)).

Directly following the Middle Weichselian (MIS 3) sub-stage, the ice margin advanced to its maximum extent at the Brandenburg moraine and other moraines on the continent and to the Main Stationary Line in Denmark in MIS 2 around 22–20 ka BP ([Houmark-Nielsen, 2004](#)).

The major ice sheets of the Pleistocene cold stages spread very rapidly. This is best documented for the Late Weichselian glaciation. As late as 24 000 BP the major Alpine valleys were still all ice free. The same is true of southern Sweden at least as far north as Göteborg. If the glacial maximum in Europe was reached at about 20 000 BP, the ice sheet must have spread at a rate of no less than 75 m year^{-1} . This calculation only takes into account the progradation of the ice margin from Sweden to North Germany. If one considers that the erratic composition of the Late Weichselian tills indicates that ice from the glaciation center advanced to the areas south of the Baltic Sea, and that melting occurred at the margin, velocities of at least $100\text{--}150 \text{ m year}^{-1}$ must be assumed. Based on varve analyses, ice advance rates of 250 m year^{-1} were reconstructed for the first Elsterian and 140 m year^{-1} for the second Saalian ice advances in the Leipzig region, Germany ([Junge, 1998](#)).

Whereas a rapid advance of the Alpine glaciers seems plausible because of the short distances and the special character of the glaciation (ice-stream network), the rapid advances of the north European and North American ice sheets are hard to comprehend using traditional explanations. Instantaneous glacierization ([Ives et al., 1975](#)) and deformable beds (after [Boulton and Jones, 1979](#)) may have played a role.

The maximum extent of the Late Weichselian ice sheet south of the Baltic Sea is rather well known. The Weichselian ice did not cross the River Elbe. For example, the Eemian deposits at Lauenburg on the River Elbe are not overlain by till. The chalk-rich tills of the Lüneburg area further to the south are of Saalian age. In eastern Germany, the ice advanced more than 200 km inland. The classic morphostratigraphical subdivision of the Weichselian Glaciation was defined in that area. Here, the Brandenburg, Frankfurt, and Pomeranian 'Stages' were originally distinguished, each of which could be subdivided into several belts of end moraines. This morphological subdivision, however, is not reflected in the stratigraphy. Till sheets of three Late Weichselian ice advances can be

distinguished in northeast Germany. The maximum Brandenburg Advance is assumed to have taken place earlier than 32 000 BP, but no precise dates are available. The Pomeranian Advance occurred about 17 600 cal BP, while the Mecklenburg Advance, which is equivalent to the Fehmarn Advance of Schleswig-Holstein, and the Young Baltic Advance in Denmark are assigned to the period around 15 000 BP. It thus coincides with the Oldest Dryas Chronozone. Its deposits are overlain by sediments of the subsequent Meindorf Interstadial. Varve counts from the Meerfelder Maar have shown that this interstadial started at 14 450 varve years BP ([Litt et al., 2007; Stephan, 2003](#)).

The present cover of unconsolidated sediments on the landscape of Scandinavia was largely formed during the last glaciation. However, in places, pre-Late Weichselian sediments have been preserved, including, for instance, sediments underlying till in Gudbrandsdalen, Norway ([Bergersen and Garnes, 1981](#)) or the Veiki moraines in northern Sweden ([Lagerbäck and Robertsson, 1988](#)). It is thought that cold-based ice in the central parts of the ice sheet helped to preserve both pre-Weichselian landforms and deposits ([Kleman et al., 2008](#)).

The Lower Vistula region of Poland is the type region of the Vistulian (Weichselian) Glaciation ([Ehlers et al., 1995](#)). Five Vistulian till units have been identified here, overlying Eemian-age marine deposits. In Poland, the maximum advance of the Vistulian Glaciation extended about 50 km south of Poznań. The ice front advanced in several lobes, the most conspicuous of which was the Vistula lobe, which extended upstream to the Plock region. In the Suwałki region, an advance of narrow ice tongues caused valley-side tectonic deformation. Subglacial drainage resulted in the formation of a dense network of meltwater channels. Proglacial outwash accumulated sandur plains (formed by glacial meltwater), the sedimentary facies of which largely resemble the North German examples. The Vistulian ice advances are dated to about 15–20 ka BP according to thermoluminescence dates or ca. 14.5–20 ka BP by radiocarbon.

The eastern margin of the last Scandinavian Ice Sheet was first mapped and studied in the 1920s–1950s. The ice limit was correlated with the German Late Weichselian maximum by means of varve chronology, which was later supported by radiocarbon dating. The ice dome discharged in the form of four large ice streams distinguished by fabrics and pebble counts. The maximum ice advance in northern Belarus occurred after the deposition of nonglacial sediments dated by radiocarbon to ca. 18 ka BP ([Velichko and Faustova, 1986](#)). Further northward in the Vologda area, the ice advance terminated ca. 18 calendar ka BP, according to accelerator mass spectrometry (AMS) radiocarbon and OSL chronology ([Lunkka et al., 2001](#)). In the far north of the Russian Plain, in the Arkhangelsk region, including the northern tip of the Kanin Peninsula in the Barents Sea, the same methods indicated that the ice front progressed eastward until 17 ka BP ([Demidov et al., 2006](#)). Thus, in Russia, the maximum ice advance appears delayed in comparison to that in Germany and the British Isles.

Traces of earlier late Pleistocene ice advances by Scandinavian ice are dubious. Since the 1950s, there has been a school professing a separate Early Weichselian glaciation ice sheet that reached the northern part of the Moscow region ([Velichko and Faustova, 1986](#)). Tills of the so-called Kalinin (or Early Valdai) Glaciation, predating the classical, less-

extensive Late Valdai Glaciation, were pictured in many maps by the Russian Geological Survey. However, this concept proved erroneous as the mass of stratigraphical descriptions show that the Mikulino (Eemian) organic sediments in the area in question either lie on the surface or are overlain only by thin soliflucted diamicton without other members of true glaciogenic deposits (Gey and Malakhovsky, 2004; Velichko and Faustova, 1986).

Moreover, no till has been found in numerous boreholes in St. Petersburg, 60°N, intervening between the Eemian marine clay and the uppermost diamicton. The Late Weichselian till is instead underlain by lacustrine sands and silts containing pollen of spruce, pine, and dwarf birch. Radiocarbon dates have given ages from 46 to 40 ka BP suggesting, if correct, that the deposits represent the first warming of the Middle Valdai 'megainterstadial.' The start of a cooling with a periglacial herb flora was dated to ca. 39 ¹⁴C ka BP. Farther south, similar subglacial sediments show a couple of additional warming events with an intermediate cooling indicated by pollen of birch parkland with xerophytic herbs (Arslanov et al., 1981). The radiocarbon dates 29–25.5 ka BP from the final warming suggest its correlation with the Denekamp Interstadial of western Europe and with the cryoturbated Bryansk paleosol, which is found to be widespread in periglacial Russia. Velichko et al. (2004) identify three relatively warm episodes within the Middle Valdai interval of 50–24 ka BP and two more interstadials within the Early Valdai Substage, all separated by cool episodes with periglacial vegetation. All short warming episodes (also the Allerød Interstadial) are marked by the pollen of boreal coniferous-birch forests. From Russia, no tills predating the Late Valdai have been described south of the Baltic Shield.

The ice recession is punctuated by several morainic assemblages located in a ~600-km-wide belt between the Valdai Upland and the Finnish border. The rank and origin of the distal hummocky agglomerations (Veps, Krestsy) is uncertain because significant readvances have not strictly been proven and radiocarbon dating of the interstadials so far is insufficient (Gey and Malakhovsky, 2004).

The most active was the Luga stadial readvance that reached up to 100–150 km south of St. Petersburg. It occurred just prior to 14.2 calendar ka BP according to paleomagnetic, varve, and AMS radiocarbon chronologies. The next phase, the Neva Phase, is dated to 13.3 calendar ka BP. After that, during the Allerød interval, the ice margin retreated rapidly from St. Petersburg to the Finnish border (some 350–500 km in 1500 years) leaving behind the largest European lakes Ladoga and Onega at the place of former major ice lobes. The last Younger Dryas Stadial readvance stood at the double Salpausselkä End Moraine complex between 12.25 and 11.6 cal ka BP (Saarnisto and Saarinen, 2001).

British/Irish Ice Sheet

Information on the extent of Early or Middle Devensian (Weichselian=MIS 4) ice in Britain is still very scarce. In England, concrete evidence for glaciation during the mid-Devensian is found only in the Lake District. Here, new evidence from boreholes indicates that valley glaciers formed in Wasdale and other valleys. At Wasdale, the ice advanced

periodically into a proglacial lake in the Ravensdale, Seascale, and Lower Wasdale areas. Early-Devensian Substage glaciation has also been reconstructed for NE Scotland, based on amino acid determinations. In Ireland, poorly dated glacial deposits may also belong to limited Middle Devensian ice sheets (Ehlers et al., 1991).

In both Britain and Ireland, the main Devensian glaciation occurred in the later part of the cold stage (MIS 2). In Britain, the Late Devensian glaciation is referred to as the Dimlington Stadial. Its glaciers advanced far south along the east coast of Britain, touching the northern coast of Norfolk. An ice tongue, following the Vale of York, advanced into Lincolnshire, damming the Trent to form proglacial Lake Humber. In the Pennines, ice flow generally followed the major valleys. The ice sheet also intruded into the Wash, damming up a lake in the southern Fenland. In the North Sea, the Dogger Bank remained ice free, but major parts of central and northern North Sea were glaciated (Bradwell et al., 2008; Clark et al., 2012).

In the Irish Sea, ice advanced far to the south, touching the south Wales coast and possibly reaching as far as the Isles of Scilly. However, many details of the glacial history are still far from clear. Not only are there problems of connecting the British and Irish stratigraphic sequences with those of continental Europe, but also with one another. The last glaciation of Ireland, the Midlandian or Fenitian Glaciation, consisted of a major Irish Ice Sheet and a smaller Kerry/Cork Ice Sheet in the southwest. The flow lines and boundaries of the ice sheets have been reconstructed from landforms, striae, and indicator erratics. For example, the distribution of Galway Granite erratics clearly demonstrates the southern extent of an Irish Ice Sheet, but this seems to have been older than the last glaciation. The distribution of periglacial features suggests that a corridor more than 50 km wide between the two Irish ice sheets remained unglaciated (Knight et al., 2004).

The dynamics of the Irish ice sheets are still hotly debated. Landforms along the west coast seem to indicate discharge of a major ice stream via Sligo Bay into the North Atlantic, forming a calving bay. Isostatic depression under the weight of the ice sheet is also demonstrated, for instance by the occurrence of an ice-contact glaciomarine delta in the Upper Carey Valley, Northern Ireland, and by shallow marine deposits at Portballintrae. Isostatic downwarping in the Irish Sea basin is also thought to have resulted in marine contact and glaciomarine deposition. The widespread occurrence of what is referred to as 'Irish Sea Till,' a shelly diamicton found on the western shores of the Irish Sea, provides the evidence for this advance. This was formerly interpreted as a product of shelf ice. In Counties Dublin and Wicklow, however, it extends to altitudes of 300 m O.D., clearly beyond any marine limit; therefore, terrestrial ice must also have been involved. As a result of glacioisostatic depression, development of a calving bay may have resulted in rapid disintegration of the combined British/Irish ice sheet at the end of the glaciation.

In northern Scotland, the Hebrides were not completely crossed by mainland ice during the Devensian Stage. There is evidence of an older glaciation that twice covered the north-western Hebridean shelf to the shelf break, but the age of these ice advances is still uncertain. The Outer Hebrides supported a local ice cap during the Late Devensian. The Inner Hebrides

and the Orkney Islands were overridden by Scottish ice during the Late Devensian, whereas Shetland and the Færøer Islands supported local ice caps. It has been postulated that parts of Scotland, mainly Caithness and Buchan, remained ice free during the last glaciation. Buchan is an area where deep pre-Quaternary weathering products have been preserved. However, more recent investigations seem to indicate that both areas were probably covered by Late Devensian ice. As on the continent, the unglaciated parts of Britain and Ireland underwent strong periglacial reworking (Ballantyne and Harris, 1994).

The extent of the Late Weichselian ice sheet in the North Sea is still a matter of debate. The distribution of buried subglacial channels on the North Sea floor suggests that the last British and Scandinavian Ice Sheets did meet. Recently, the investigation of sediment cores has shown that both ice sheets were in contact in the northern North Sea. AMS radiocarbon dates show that this event took place rather early, between 29 400 and ca. 22 000 BP. This ice advance thus predates the Late Devensian Dimlington Stadial.

The Alps

At the northern shore of Lake Mondsee (Austria), a thick sequence of limnic deposits was exposed, both over- and underlain by till. Palynological investigations revealed that the lake deposits comprised the last interglacial plus four Early Weichselian interstadials. The Eemian vegetational succession closely resembles that of Samerberg. The climatic optimum is represented by a mixed oak forest, which is rich in *Ilex* and *Taxus*. This suggests that the mean annual temperature in the Eemian was some 2–3 °C warmer than during the Holocene climatic optimum. At the end of the Eemian, similar to northern Germany, complete deforestation followed. The Early Weichselian interstadials saw a reimmigration of trees. The interstadial forest was dominated by *Picea* and, to a lesser degree, also by *Quercus* (oak) and *Taxus* (ash) (Drescher-Schneider, 2000).

In the Alps, initially a single undivided Würmian Glaciation was envisaged, subdivided only by a series of recessional end moraines. However, today it is quite clear that the Alps, like northern Europe and North America, experienced a Mid-Würmian ice advance. Only its extent is still a matter of debate.

Based on stratigraphical investigations at Thalgut, Jaberg, Thungschneit, and Cossonay, it can be said that the last cold stage in Switzerland was represented by two major ice advances, the glaciers of which reached well into the alpine foreland, the earlier having been less extensive than the later ice advance. The sections at Gossau and at Walensee indicate that, from 60 000 to 28 000 BP, an ice-free period occurred between the two ice advances. In this period, three interstadials occurred, all characterized by coniferous forest (Schlüchter, 2004). At Wangen on the River Aare, an erratic block on the Würmian moraine could be dated by cosmogenic nuclides at $20\,100 \pm 1000$ years BP (Ivy-Ochs et al., 2004). Also, in the French Alps, the main advance of the Würmian ice has been dated to around 20 000 BP (Buoncristiani and Campy, 2004).

In contrast to the results from France and Switzerland, the Samerberg (Bavaria) and Mondsee (Austria) profiles show an uninterrupted sequence of lake sediments between unequivocal deposits of the Riss/Würm Interglacial (Eemian Stage) and the Late Würmian till (approximately 20 000 BP). Also, in the Austrian Traun valley, traces of only one Würmian ice advance have been found. Here, there is no evidence of a possible advance during the Early or Middle Würmian Substages. The main ice advance of the last glaciation accordingly started only after 25 000–24 000 BP and reached its maximum around 20 000 BP as in northern Europe (van Husen, 2011). The extent of the Würmian glacial maximum is shown in Figure 7.

Within the area of the last glaciation, extensive accumulations of lake sediments that are assigned to the Middle Würmian by means of radiocarbon dating have been preserved in some places. The most prominent occurrence of pre-Late Würmian lacustrine deposits are the varved clays of Baumkirchen, 12 km east of Innsbruck, which seem to postdate the Middle Würmian interstadial. During their deposition, the

Figure 7 Extent of the Würmian Alpine glaciation. Reproduced from Ehlers J (2011) *Das Eiszeitalter*, p. 363. Heidelberg: Spektrum.

climate was already rather cool: in the vicinity of the lake shrub, tundra was dominant. The sequence of varved clays, over a hundred meters thick, is overlain by ~70 m of outwash gravels, which are, in turn, covered by a thick till. The varved clays were deposited in a shallow lake, as indicated by trace fossils of fish on the bedding planes. The sedimentation rate was constantly high, reaching an average of 5 cm per year. At Baumkirchen, the boundary between the Middle and Late Würmian Substages has been defined. Radiocarbon dates on wood (*Pinus*, *Alnus*, and *Hippophae*) from the varved clays have yielded ages of between $31\,600 \pm 1300$ and $26\,800 \pm 1300$ years, giving a maximum age for the Late Würmian glaciation (Fliri, 1973).

In contrast to the Scandinavian glaciation area, where the thickness of the ice can be determined only at very few points because of the almost total absence of nunataks, the maximum height of the Alpine ice streams can be precisely reconstructed by mapping the upper limits of erratics. During the Würmian glacial maximum, transfluence occurred at various points of the ice-stream network. In the Inn valley, for instance, around Landeck, five tributary glaciers merged to form one major valley glacier, advancing eastward down the Inn valley. At the same time, a major tributary glacier from the south had already blocked the Inn valley around Innsbruck. Congestion resulted in a rise of the ice surface until the threshold to the north was finally crossed, and ice from the Inn valley flowed over the Fernpass and the Seefelder Senke due north into the Isar and Loisach drainage systems. Such events are reflected in the supply of gravel and major erratics. In the foreland of the Isar–Loisach Glacier, Alpine crystalline rocks constitute up to 35% of the total, in the 20–31.5 mm fraction. In contrast, in the Tölz Glacier lobe, adjoining the east, the contents range only between 0 and 1%, as no ice crossed over from the Inn valley (Dreesbach, 1985).

Both north and south of the Alpine main ranges, the Late Würmian glacial maximum was followed by a long stillstand during which the ice margin stagnated within a few hundred meters behind the outermost moraine. During this halt, a morphologically more distinct end moraine than that during the Würmian maximum accumulated, and the main gravel body of the Lower Terrace also originated from the position of this moraine. Glaciers rapidly collapsed before 17 500 BP. A series of minor readvances occurred during the Late Glacial, but the glaciers barely reached the main Alpine valleys. The last of these advances formed the Egesen moraine at about 11 800 BP, that is, during the Younger Dryas Chronozone (Jerz, 1993).

Other Areas

There are other formerly glaciated areas, such as the Pyrenees, the Carpathians, and the Caucasus, or the high mountains of Italy, Greece, Turkey, and the Balkans, which provide interesting information on former glaciation levels and equilibrium line altitudes.

Many of the other Asian mountain ranges, such as the Verkhoyansk Mountains, the Jablonovyi, or the mountains of Kamchatka, have not yet been mapped in any detail, and comparison of the available maps with satellite imagery or a

Digital Elevation Model makes it immediately clear that much more work is needed in those areas. Remote sensing provides excellent tools to start such investigations, with imagery up to a scale of over 1:5000 available through the QuickBird and Ikonos satellites. However, apart from all the technical progress, the decisive work to answer the open questions will still need to be done in the field.

Deglaciation

The end of the Weichselian cold stage is characterized by a number of climatic oscillations, which for a long time have been used for stratigraphical subdivision (Mangerud et al., 1974). Especially the mild Bølling and Allerød interstadials, and the cold Younger Dryas stadial are seen in a number of proxy records such as pollen, beetles, and marine fossils, in addition to the glacial fluctuations.

Bock et al. (1985) also distinguished the Meiendorf Interstadial before the Bølling. According to the distribution of *Hippophae* in North Germany, the Meiendorf Interstadial might have had climatic conditions similar to the Allerød Interstadial, although there were no trees. During the Allerød, North Germany and adjoining areas were covered by a mixed forest of birch and pine.

A consistent mapping of the pattern of the deglaciation has turned out to be difficult. One reason for this is that the deglaciation was driven by different forces. Certainly, warmer summers were the main factor driving the ice retreat and the dominant factor in determining where the ice sheet ended on land. However, much of the ice margin was located in lakes, particularly the Baltic Ice Lake, and along the western margin in the sea, and in these areas calving and sea-water temperature were more important factors. It is a common feature that the ice in the fjords broke up before the adjacent land was ice free.

The extent of the Younger Dryas readvance is well known (Figure 8). The Younger Dryas moraines are the only moraines that can be mapped continuously around the entire Scandinavian Ice Sheet (Andersen et al., 1995a). The interpretation of the main pattern is that summers became colder and thus the retreat halted, or there was a readvance. A number of differences in reactions are, however, superimposed on this main pattern. In western Norway, there was a readvance that started during the late Allerød and continued to the very end of the Younger Dryas (Bondevik and Mangerud, 2002; Lohne et al., 2007), whereas in Trøndelag, some 400 km farther north, the ice margin retreated during the Younger Dryas (Andersen et al., 1995b). This means that in some places around Scandinavia, the outermost Younger Dryas moraines were formed at the beginning of the Younger Dryas, whereas in other areas they were formed at the very end. The Baltic Ice Lake was drained and the Baltic connected to the sea at the end of the Younger Dryas (Lundqvist, 2004) to form the Yoldia Sea (Figure 9).

Late Quaternary in Highland Asia

L A Owen, University of Cincinnati, Cincinnati, OH, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

Central Asia is home to the world's greatest topography that includes the mountains of the Himalaya, Tibet, Pamir, Tien Shan, and Altai, which together constitute Highland Asia (Figure 1). Within Highland Asia, the Himalaya, the Trans Himalaya, and the Tibetan Plateau are by far the most striking and stretch E–W for ~2000 km from Burma to Afghanistan and northward for ~1500 km from India to central China, with Tibet having an average elevation of ~5000 m above sea level (asl). The average elevation for the Himalaya and the Trans Himalaya is less, but they contain numerous peaks that exceed 6000 m asl and all of the world's 8000 m high peaks. The region also has the land's greatest relative relief, which commonly exceeds several kilometers. Together, the mountains of Highland Asia form the most glaciated track outside of the Polar Region and they have a profound influence on regional and global atmospheric circulation, and the hydrology of some of the world's greatest rivers, which include the Indus, the Ganges, the Yellow River, and the Yangtze (Lehmkuhl and Owen, 2005).

Four major climatic systems influence the region, which include (1) the mid-latitude westerlies, (2) the south Asian monsoon, (3) the Mongolian high-pressure system, and (4) the El Niño Southern Oscillation (ENSO). The relative importance of these climate systems varies throughout the region and has likely varied significantly, both spatially and temporally throughout the Quaternary (Lehmkuhl and Owen, 2005). Presently, the southern slopes of the Himalaya and the high mountains of eastern Tibet receive snowfall mainly in the summer monsoon season. In contrast, northern and western Tibet, and ranges such as the Karakoram Mountains, Pamir, Tien Shan, and Altai, receive heavy snowfall during the winter with moisture supplied from the mid-latitude westerlies and the Mongolian high-pressure system. This snow supports ice caps and valley glaciers throughout Tibet and the bordering mountains. The regional snowline varies significantly throughout the region; for example, it is 4600–5600 m asl and 6000–6200 m asl south and north of Everest, respectively, 5200–5700 m asl in the Garhwal Himalaya, 4500–4700 m asl around Nanga Parbat, 4600–5300 m asl on the south side of the Karakoram Mountains, and 5200–5700 m asl on the northern side of the Karakoram (Owen and Benn, 2005 and references therein). The glacial and hydrological systems in these mountains provide water for hundreds of millions of people in central Asia and understanding the spatial and temporal variations in climate, glaciation, and hydrology clearly has important socioeconomic implications.

In recent years, there has been increasing recognition of the geologic, climatic, and anthropogenic importance of the region. This has resulted in an increasing number of studies on the nature, extent, and precise timing of glaciation. Many of these studies have involved detailed fieldwork, the application

of newly developing remote sensing technologies, and extensive programs of numerical dating. Yet, there is much more to be known about Late Quaternary glaciation, and the associated hydrological and climatic responses are presently very poorly defined. This is partially due to the logistical and political inaccessibility of the region; it also reflects the continued need to develop more precise ways to reconstruct the extent and to define the timing of former glacial events.

Intense fluvial and glacial erosion within the mountains of High Asia often destroys diagnostic morphologies of glacial and mass movement landforms, making their identification difficult. In addition, diamictos that comprise mass movement and glacial landforms look very similar and have similar particle size distributions and particle shapes. The misinterpretation of glacial and mass movement landforms and sediments within many of the ranges in Highland Asia has led to erroneous reconstructions of former glacier extent (Hewitt, 1999). In some cases, this has resulted in overestimates of glacial extent, and in an extreme case has helped perpetuate the theory that an extensive ice sheet covered Tibet during the last glacial cycle (Kuhle, 1985). The existence of extensive ice sheet on Tibet was hotly debated during the 1990s, but is no longer considered plausible based on the geologic evidence now available (Owen et al., 1998, 2005; Rutter, 1995; Schäfer et al., 2002; Seong et al., 2008). To provide a framework for accurate glacial reconstructions in Highland Asia, Benn and Owen (2002) provided a review and presented new studies on the sedimentology and geomorphology of Himalayan glaciers to aid and help emphasize the need for detailed analysis of landforms using modern sedimentological techniques.

The lack of organic material preserved in glacial and associated landforms and sediments throughout much of Highland Asia has inhibited the use of radiocarbon dating to help define the timing of glaciation, and where present, most organic matter is Holocene in age (Owen, 2009). However, with the rapid development and application of optically stimulated luminescence (OSL) and terrestrial cosmogenic nuclide (TCN) surface exposure dating throughout the early part of the twenty-first century, many of the glacial successions throughout Highland Asia have been dated (e.g., Barnard et al., 2006; Dortch et al., 2010; Finkel et al., 2005; Hedrick et al., 2011; Owen et al., 2001, 2002b, 2003a,b,c, 2005, 2006a,b, 2008, 2009, 2010; Phillips et al., 2000; Richards et al., 2000a,b; Schäfer et al., 2002, 2008; Scherler et al., 2010; Seong et al., 2007, 2009; Tsukamoto et al., 2002; Zech et al., 2005, 2009). Although both techniques have inherent and associated problems (Fuchs and Owen, 2008; Owen et al., 2008), careful sampling design (Benn and Owen, 2002) and combining the two sets of methods have enabled robust chronologies to be developed (e.g., Owen et al., 2009).

Schäfer et al. (2008), for example, illustrated some of the challenges in applying TCN methods to dating moraines in their study of the glacial successions in Nyalam County in the

Figure 1 Digital elevation model of Highland Asia showing the main regions where modern detail glacial chronologies have been developed and that are discussed in this article.

monsoonal Himalaya, and suggested that the inconsistencies in their ages reflected times of enhanced weathering. Owen et al. (2008) emphasized that limits to the precision and accuracy of available dating methods and, more importantly, the geological uncertainty imposed by both processes of moraine formation and alteration conspire to limit the time resolution on which correlations can be made to Milankovitch timescales. To put all studies on a common scale, Owen et al. (2009) reevaluated well-dated sites and recalculated all the published ^{10}Be TCN ages for moraine boulders and glacially eroded surfaces throughout the Himalaya and Tibet. The study showed that locally there are considerable variations in the extent of glaciation from one region to the next during a glaciation. Moreover, glaciers throughout monsoon-influenced Tibet, the Himalaya, and the Trans Himalaya were likely synchronous both with climate change resulting from oscillations in the South Asian monsoon and Northern Hemisphere cooling cycles. In contrast, Owen et al. (2008) showed that glaciers in the Pamir in the far western regions of the Himalayan–Tibet orogen advanced asynchronously relative to the other regions that are monsoon-influenced, and glaciers in the Pamir appear to be mainly in phase with Northern Hemisphere cooling cycles.

Compilations of research on the Quaternary glaciation of Highland Asia are presented in several volumes of *Quaternary International* (Owen and Lehmkuhl, 2000; Owen and Zhou, 2002; Schwab, 2010; Yi and Owen, 2006; Yi et al., 2011), reviewed by Lehmkuhl and Owen (2005), Owen et al. (2008), and Owen (2009), and glacial mapping and chronologies are summarized for the Global Mapping Project of INQUA in Ehlers and Gibbard (2004, 2011). The best summary map of the extent of glaciation throughout Highland Asia during the last glacial was produced by Shi (1992; Figure 2). To summarize the current knowledge on the nature of

Quaternary glaciation in Highland Asia, this article considers each major region in turn.

Himalaya and Trans Himalaya

Owen et al. (1998, 2002a, 2008), Lehmkuhl and Owen (2005), and Owen (2009) provide reviews of the Quaternary glacial history of the Himalaya, and Ehlers and Gibbard (2004, 2011) provide further descriptions of the Quaternary glacial history of each Himalayan region. Simplified summaries to show the timing of glacial advances for each of the main regions in Highland Asia that have been studied using modern numerical dating methods are shown in Figure 3.

Glacial geologic studies throughout the Himalaya and the Trans Himalaya during the last decade have been quite detailed, and numerous glacial advances have been dated in selected regions. Of note is the work of Seong et al. (2007) in the Central Karakoram, where four glacial stages are defined using ^{10}Be TCN dating to >0.7 Ma, marine oxygen isotope stage (MIS) 6 or older, MIS 2, and the Holocene. Glaciers advanced several times during each glacial stage. Glacial advances are not well defined for the oldest glacial stages, but the younger glacial advances likely occurred at ~16, ~11–13, ~5, and ~0.8 ka. Scherler et al. (2010) provided ^{10}Be TCN ages to define five glacial episodes at ~16, ~11–12, ~8–9, ~5, and <1 ka in the Tons, Thangro, and Pin valleys in the Garhwal Himalaya. These glacial advances were attributed to glacial–interglacial oscillations related to waxing and waning of the Northern Hemisphere ice sheets, while the timing of millennial-scale oscillations was related more directly to monsoon strength. Similarly, around Annapurna, Zech et al. (2009) applied ^{10}Be TCN dating to define the landsliding and alluviation to help

Figure 2 Reconstruction for the former extent of glaciation across Tibet and the bordering mountains for the maximum extent of glaciation during the last glacial (after Shi, 1992 from Owen, 2009). This reconstruction was based on detailed field mapping of glacial and associated landforms and sediments.

Figure 3 Simplified glacial chronologies for the Late Quaternary (back to 100 ka) that have been numerically dated throughout the Himalaya and Tibet. The black bars represent times of glacial advance (adapted from Owen LA, Caffee MW, Finkel RC, and Seong BY (2008) Quaternary glaciations in the Himalayan-Tibetan orogen. *Journal of Quaternary Science* 23: 513–532; Owen LA (2009) Latest Pleistocene and Holocene glacier fluctuations in the Himalaya and Tibet. *Quaternary Science Reviews* 28: 2150–2164; and data from Abramowski et al., 2006; Barnard et al., 2004a,b, 2006a,b; Chevalier et al., 2005; Colgan et al., 2006; Dortch et al., 2010; Finkel et al., 2003; Meriaux et al., 2004; Owen et al., 2001, 2002b,c, 2003a,b,c, 2005, 2006a,b; Phillips et al., 2000; Richards et al., 2000a,b; Schäfer et al., 2002, 2008; Scherler et al., 2010; Seong et al., 2007, 2008; Sharma and Owen, 1996; Shiraiwa, 1993; Spencer and Owen, 2004; Tsukamoto et al., 2002; Yi et al., 2002; Zech et al., 2003, 2005, 2009). See Figure 1 for the locations of each study area. The marine oxygen isotope stages (MISs) are shown to the far right.

constrain the timing of deglaciation. They suggested that some glaciers advanced in-phase with Northern Hemisphere ice sheets, whereas others reached their maximum extent at times of increased monsoonal precipitation during MIS 3 and the early Holocene.

In a study on Mount Everest, Owen et al. (2009) showed using OSL and ^{10}Be TCN dating that glaciations across the Everest massif were broadly synchronous. However, unlike the southern slopes of Mount Everest, no early Holocene glacier advance was recognized on its northern slopes. Owen et al.

(2009) suggested that the southern slopes may have received increased monsoon precipitation in the early Holocene to help increase positive glacier mass balances, while the northern slopes were too sheltered to receive monsoon moisture during this time and glaciers could not advance. Comparing equilibrium-line altitude (ELA) depressions for glacial stages across Mount Everest, Owen et al. (2009) revealed asymmetric patterns of glacier retreat that likely reflect greater glacier sensitivity to climate change on the northern slopes, possibly due to precipitation starvation (Figure 4). This illustrates some of the sharp contrasts in the degree of glaciation across relatively short geographical distances.

To generalize, glaciation in many regions throughout the northern areas of the Himalaya and the Trans Himalaya was very much restricted during the global Last Glacial Maximum (LGM), with glaciers generally advancing <10 km from contemporary ice margins. The local LGM, however, occurred during the early part of the last glacial cycle, and in many regions, this was during MIS 3 (e.g., Dortch et al., 2010; Finkel et al., 2003; Owen et al., 2009; Richards et al., 2000b; Seong et al., 2007). In contrast, in the southern, more monsoon-influenced areas of the Himalaya, glacier advances during the LGM were more extensive and often it is difficult to find evidence for pre-LGM glaciation (e.g., Barnard et al., 2006).

Figure 4 Example of modern glacial reconstructions and chronologies for a mountain mass in Highland Asia, provided by Mount Everest. Reproduced from Owen LA, Robinson R, Benn DI, et al. (2009) Quaternary glaciation of Mount Everest. *Quaternary Science Reviews* 28: 1412–1433. (a) Reconstructions of the glacial extent across Mount Everest plotted on a digital elevation model for (left to right): the Jilong ($\sim 24.3 \pm 3.8$ ka) and Periche I (23.9 ± 2.5 ka) glacial stages, Rongbuk (16.6 ± 4.1 ka) and Periche II (17.0 ± 1.7 ka) glacial stages, and the Samdupo I (7.1 ± 0.5 ka) and Chhukung (10.1 ± 0.4 ka) glacial stages. Ages shown are based on ^{10}Be TCN dates except for Samdupo I, which is based on OSL dating. (b) Profile across Everest showing ELA reconstructions for the Jilong, Periche I, Rongbuk, Periche II, Samdupo I, and Chhukung glacial stages (the profile line is shown in part A).

The complexity in the timing and style of glaciation across Highland Asia supports the view of [Benn and Owen \(1998\)](#) that glaciation throughout much of the region was asynchronous with the Northern Hemisphere ice sheets and oceans, with the maximum glacial advances occurring during MIS 3 or MIS 5a to 5d. The timing of these advances is attributed to increased cloud cover and precipitation as snow at high altitudes due to a strengthened monsoon that penetrated further north into the Himalaya and Trans Himalaya during times of increased insolation ([Finkel et al., 2003](#); [Owen et al., 2002b, 2005](#)). During times of lower insolation, particularly during the global LGM (MIS 2), the influence of the monsoon was reduced in the northern areas of the Himalaya and the Trans Himalaya, which in turn resulted in lower snowfall and snow accumulation, and hence less extensive glaciation. In contrast, in the southern regions of the Himalaya, significant moisture and cloud cover enabled glaciers to grow in times of lower insolation and reduced temperatures.

Many glaciers throughout the Himalayan and Trans Himalayan regions have been retreating throughout the last century ([Fujita et al., 1997](#); [Mayewski and Jeschke, 1979](#); [Mayewski et al., 1980](#)), but the extent of retreat has yet to be adequately quantified. However, in some regions such as Karakoram, glaciers have been remarkably stable and some glaciers have thickened and surged over the last decade or so ([Copland et al., 2011](#); [Mayer et al., 2006](#)). This may be coincident with a period of increased precipitation and positive glacier mass balance in the Karakoram. Possible widespread deglaciation, particularly the uncertainty in the degree of likely change, poses a serious threat to water resources on the Indian subcontinent and may result in hazards such as glacial lake outburst floods ([Richardson and Reynolds, 2000](#)).

Tibet

The existence of an extensive ice sheet was one of the most contentious glacial issues concerning the Quaternary glaciation of Tibet during the latter part of the twentieth century. The existence of an ice sheet was mainly stimulated by the work of Kuhle (e.g., [Kuhle, 1985](#)); however, numerous publications discuss the evidence against an extensive ice sheet, and it is now generally accepted that a large ice sheet did not exist on the Tibetan Plateau during at least the last few glacial cycles ([Lehmkuhl and Owen, 2005](#); [Owen et al., 1998, 2005](#); [Rutter, 1995](#); [Schäfer et al., 2002](#); [Seong et al., 2008](#)). [Liu et al. \(1988\)](#), [Li et al. \(1991\)](#), and [Shi \(1992\)](#) provide the most widely accepted regional reconstructions of the former extent of glaciers across the Tibetan Plateau ([Figure 2](#)).

The general style of glaciation in Tibet appears to have changed over the last several glacial cycles from expanded ice caps, to piedmont-style glaciers, and then to entrenched valley glaciers ([Lehmkuhl et al., 2002](#); [Owen et al., 2003, 2005, 2010](#); [Schäfer et al., 2002](#)). This is well illustrated by [Owen et al. \(2010\)](#) who examined the evidence for glaciation in and around Gurla Mandhata (Naimona'nyi), an isolated massif in southern Tibet, and developed one of the most well-defined numerically dated glacial successions for the region. [Owen et al. \(2009\)](#) were able to show that glaciation changed from an expanded ice cap that stretched ~5 km into the foreland of

the Gurla Mandhata massif, likely during MIS 10 or an earlier glacial cycle, to piedmont-type glaciation probably during the early part of the last glacial cycle or the penultimate glacial cycle, after which glaciers became restricted to entrenched valley types. Impressive laterofrontal moraines at the mouths of most valleys date to the early part of the last glacial cycle and MIS 3. A succession of six sets of moraines within the valleys and up to the contemporary glaciers shows that glaciers advanced during the Late Glacial, early Holocene, Neoglacial, and possibly, Little Ice Age. [Owen et al. \(2010\)](#) suggested that the change of style of glaciation throughout the latter part of the Quaternary, from expanded ice caps to deeply entrenched valley glaciers, might reflect climatic controls with reduced moisture supply to the region over time and/or tectonic controls reflecting increased basin subsidence due to detachment faulting and enhanced valley incision.

As in the Himalaya, the local LGM in Tibet appears to have been early in the last glacial cycle ([Owen et al., 2003, 2005, 2010](#); [Schäfer et al., 2002](#)). This might reflect increased moisture flux, and cloudiness during these times created higher precipitation in the form of snow at high altitude, which in turn led to positive glacial mass balances and glacial advances. However, although precipitation would have been reduced during the insolation minima of MIS 2 (global LGM), temperatures were low enough to lead to positive glacier mass balances, allowing glaciers to advance, albeit not as very far as to the local LGM limits.

The few published studies on Late Glacial and Holocene glacier fluctuations in Tibet suggest that glaciers advanced at 2–15 ka in the West Kunlun and in the mountainous areas surrounding the Qaidam Basin, and advanced during the early Holocene advances in the Anyemaqen, Gurla Mandhata, on the Karola Pass, and in the Gongga Shan during the early Holocene ([Lehmkuhl and Owen, 2005](#); [Owen et al., 2005, 2006b, 2010](#)). Little Ice Age and Neoglacial moraines are defined by dates on wood and branches incorporated in moraines for several regions ([Lehmkuhl and Owen, 2005](#) and references therein). [Su and Shi \(2002\)](#) discuss the nature of glacial fluctuations since the Little Ice Age (seventeenth to nineteenth century) and show that the mean temperature of monsoonal temperate glaciers in China has increased by 0.8 °C with a decrease in modern glacier area of ~30%, a loss of some 4000 km².

Tien Shan and Altai Mountains

Until recently, there was much debate concerning the extent of late Pleistocene glaciation in the Tien Shan and Altai Mountains. [Grosswald et al. \(1994\)](#), for example, argued that an extensive ice sheet existed in these regions during the last glacial cycle, with late Pleistocene glaciers extending to the foothills of the Tien Shan. However, other arguments and recent studies provide evidence that glaciers were restricted to the mountain range and did not reach the foothills ([Heuberger and Sgibnev, 1998](#); [Koppes et al., 2008](#); [Zech et al., 1996](#)).

The first comprehensive study of moraine successions in the Tien Shan was undertaken by [Koppes et al. \(2008\)](#) who used numerical ¹⁰Be TCN dating methods to define the ages of glacial advances. [Koppes et al. \(2008\)](#) showed that glaciers in

the north and east of the Kyrgyz Tien Shan last advanced to their maximum positions during MIS 5 and again during MIS 4, while in the south and west of the range, glacier advances occurred during MIS 3. In contrast to maritime Europe and North America, there was no evidence of a major glacial advance during MIS 2, and glacier advances during MIS 2 and since were restricted to the vicinity of modern glaciers. [Koppes et al. \(2008\)](#) also support the view that an extensive ice sheet did not exist in the region.

In the NW Tien Shan, [Kong et al. \(2009\)](#) presented ^{10}Be ages ranging from 9 to 21 ka on glacial boulders at the head of the Urumqi River and suggested that glacial advance and retreat commenced at the global LGM and most likely abated by the early Holocene.

Valley glaciers reached Lake Teleski at 430 m asl in the Russian Altai, with the extent of glaciation being greatest in the western Russian Altai ([Lehmkuhl and Owen, 2005](#), and references therein). In the eastern region, valley glaciers stretched down to the Kuray and Chuya Basins damming the main rivers to form ice-dammed lakes, which ultimately produced the largest glacial lake outburst floods in the world ([Baker et al., 1993](#); [Rudoy, 2002](#)). In the eastern part of the Russian Altai and the Mongolian Altai, [Lehmkuhl \(1998\)](#), [Klinge et al. \(2003\)](#), and [Lehmkuhl et al. \(2004\)](#) provide evidence for two major Pleistocene glaciations of a similar extent. The limited extent of the present and Pleistocene glaciers in the western part of the Russian Altai and in the Mongolian Altai is the result of reduced precipitation from west to east, which causes a rise of present and Pleistocene ELAs toward the east. Although there is a lack of numerical dating of glacial sediments and landforms in this region, [Lehmkuhl et al. \(2004\)](#) argued that most late Pleistocene glacier advances in Mongolia and in the Russian Altai took place during MIS 2 and 4.

Pamir

The nature of Late Quaternary glaciation in the Pamir of Tajikistan has been examined by [Zech et al. \(2005\)](#) who mapped moraines southwest of Lake Yashilkul and applied ^{10}Be TCN surface exposure methods. [Zech et al. \(2005\)](#) recognized three main glacial advances, which included an extensive glaciation at ~ 60 ka, a less extensive glacial advance at or before 47 ka, and an even more restricted glacial advance during the latter part of the last glacial. The pattern of progressively limited glacial extent during the late Pleistocene was attributed to increasing aridity in the Pamir ([Zech et al., 2005](#)).

In the easternmost Pamir, [Seong et al. \(2009\)](#) studied the glacial record of two massifs, Muztag Ata and Kongur Shan. Using remote sensing, field mapping, and ^{10}Be TCN methods, [Seong et al. \(2009\)](#) showed that glaciers advanced at least 12 times during at least the last two glacial cycles. Over this time, the style of glaciation changed progressively from one that produced ice caps to one that produced less extensive and more deeply entrenched valley glaciers. [Seong et al. \(2009\)](#) suggested that this might reflect increasing aridity over time, which might be influenced by tectonics. The timing of the two earliest glaciations, however, was poorly defined, but likely occurred prior to the penultimate glacial cycle, the early part

of the last glacial cycle, or during the penultimate glacial cycle. The younger glacial advances were relatively well defined showing quasiperiodical oscillations on millennial timescales at ~ 17.1 , ~ 13.7 , ~ 11.2 , ~ 10.2 , ~ 8.4 , ~ 6.7 , ~ 4.2 , ~ 3.3 , ~ 1.4 ka, and a few hundred years before the present. [Seong et al. \(2009\)](#) argued that since the global LGM, the glaciers in the easternmost Pamir and westernmost Tibet were likely responding to Northern Hemisphere climate oscillations (rapid climate changes), with minor influences from the south Asian monsoon.

Equilibrium-Line Altitudes

Reconstructions of past ELAs for glaciers throughout Highland Asia are summarized in [Owen and Benn \(2005\)](#). [Owen and Benn \(2005\)](#) and [Benn et al. \(2005\)](#) stressed the need to use multiple methods when reconstructing past and present ELAs for high-altitude glaciers, which are strongly influenced by topography and have extensive supraglacial debris cover. Even though much numerical dating has been undertaken in recent years, there are few studies that combine chronostratigraphies and ELA studies. This makes it particularly difficult to reconstruct patterns of ELAs across large areas of Highland Asia. Using the two best dated moraine successions in the Himalaya and Tibet, namely the Hunza Valley and the Khumbu Himal, [Owen and Benn \(2005\)](#) and [Owen et al. \(2009\)](#) calculated the ELA for MIS 2 (global LGM) to show that for these regions, the ELA depression during MIS 2 was ~ 200 – 300 m and ≤ 100 m, respectively. This contrasts sharply with earlier estimates for the ELA depression for these regions, which were estimated to be > 500 m, and it helps highlight how restricted glacial advances were during the global LGM for large areas of Highland Asia. [Owen et al. \(2009\)](#) also provide ELA reconstructions across Mount Everest for different numerically dated glacial advances during the Late Quaternary ([Figure 4](#)).

Broad regional ELA gradients can be reconstructed across Highland Asia even though there are significant problems correlating glacial successions and reconstructions of ELA depressions. [Lehmkuhl and Owen \(2005\)](#) provide illustrations that show present and Pleistocene glaciers and ELAs, which crudely quantify the nature of glaciation in some of the high mountains of Highland Asia ([Figure 5](#)). These show that ELAs dropped by 300–500 m in the drier parts and by 600 to more than 1000 m in the wetter parts of the Tibetan Plateau and the Himalaya sometime during the last glacial cycle, but in some areas, these ELA depressions might actually be for a previous glacial cycle as many are not defined by numerical dating.

Conclusion

An understanding of the nature, timing, and extent of late Quaternary glaciation in Highland Asia is rapidly advancing, but the vastness and inaccessibility of the region still presents significant challenges. With the development and application of new dating techniques, specifically TCN and OSL dating, the number of glacial successions that have been dated during the last decade is encouraging. The numerical dating studies suggest that on millennial timescales glaciation is broadly

Figure 5 Selected cross-sections of Central and High Asia, including the distribution of present and local Last Glacial Maximum ice and the ELAs. Adapted from Lehmkuhl F and Owen LA (2005) Late Quaternary glaciation of Tibet and the bordering mountains: A review. *Boreas* 34: 87–100. Cross-section A–A' – the Russian Altai to the Mongolian Altai. Cross-section B–B' – eastern fringe of the Tibetan Plateau. Cross-section C–C' – Khangay and Gobi Altai to the Tibetan Plateau. Cross-section D–D' – southern Tibet. The inset map in the top right corner shows the variation in contemporary regional snowlines across Tibet and the bordering mountains.

synchronous throughout Highland Asia, but the exact timing and extent of glaciation varies considerably within and between different mountain ranges within Highland Asia. The complex patterns of glaciation that are emerging imply that the glaciation throughout High Asia reflects varying, temporally and spatially, forcing by the different climatic systems that dominate the region. As such, the style and timing of glaciation appears to be strongly controlled by climatic gradients, but topography may also have an important control. The extent of glaciation has become increasingly restricted throughout the Late Quaternary in the more arid regions of Highland Asia, which has helped preserve very old (pre-last glacial cycle) glacial landforms. In contrast, in regions that are very strongly influenced by the monsoon, the preservation potential of old moraine (pre-Late Glacial) is poor. This may be because Late Glacial and Holocene glacial advances were most extensive, destroying the geomorphic or sedimentary evidence of earlier glaciations, together with the intense fluvial and mass movement denudation that is characteristic of the wetter regions. Neoglacial, Little Ice Age, and historical moraines testify to a progressive retreat of glaciers during the twentieth century and warn of a continued retreat during the coming century.

Late Quaternary in North America

J T Andrews, University of Colorado, Denver, CO, USA

This article is reproduced from the previous edition, volume 2, pp. 1095–1101, © 2007, Elsevier B.V.

The structure of late Pleistocene glaciations is now well-known at the global scale because of the intimate association between global sea levels and ice volumes. Measurements of the stable isotopic composition of benthic Foraminifera and surveys of raised marine terraces from tectonically uplifting areas have provided this template (Chappell et al., 1996). However, the extent to which individual ice sheets or continental ice complexes mirror the global pattern is unclear, especially for those events that exceed the reliable limits of radiocarbon dating. Here, we take that limit to be in the range of 40–50 cal ka BP, but dating the interval between ~20 and 50 cal ka BP is often problematic because the samples are more than four half-lives old and contamination by small amounts of younger carbon results in apparent ages that are much too young. The global pattern of changes in ice volume has been correlated with variations in the solar insolation in the Northern Hemisphere, often represented by changes at 65°N, and attributed to changes in the so-called Milankovitch orbital forcings (Budd and Smith, 1981; Imbrie et al., 1993) (Figure 1).

At the global scale, using the Marine Isotope Stage (MIS) designations, the last interglacial (MIS substage 5e) was followed by a series of glacial (MIS substages 5b and 5d) and interstadial events (MIS substages 5a and 5c), which were followed in turn by a long period of ice sheet growth during MIS 4. MIS 3 is an interval of 'interstadial' conditions positioned between the major glacial events of MIS 4 and MIS 2 (Figure 1). At the termination of the latest glacial cycle, Northern Hemisphere insolation rose rapidly, and to this rise is attributed the disappearance of many of the world's large ice sheets and glaciers—all except the Greenland and Antarctica ice sheets.

The view of late Pleistocene glaciations embodied in Figure 1, or in deep-sea benthic isotope curves, is dominated by the relatively slow and predictable Milankovitch forcings at ~20, 40, and 100 ka. Ice sheet behavior is thus seen as predictable and driven largely by changes in insolation and associated changes in temperature and precipitation. However, the earth's climate is and has been spatially variable. Changes in ice volumes are linked to the balance between accumulation and ablation, and there is no reason *a priori* to expect synchronicity of changes in mass balance for all parts of large ice sheets that span 45° of latitude. Furthermore, as ice sheets and outlet glaciers encroach onto continental shelves, and especially as they move seaward toward the shelf break, their mass balance changes will be due to nonclimatic forcings, such as relative sea level, which will be controlled by regional rates of glacial isostatic depression or rebound. For example, calving rates are strongly dependant on water depth at the ice margin and the slope of the sea floor (Hughes, 1987; Clarke et al., 1999). The same would also apply as ice sheets advanced into or retreated from large glacial lakes. These calving events will

clearly influence the mass balance of entire ice drainage basins and thus significantly control the position of ice margins.

Although this article pertains to 'North America,' the focus is on the large ice sheets that covered much of the land north of 40°N during MIS 2, which includes the Cordilleran, Laurentide, and Innuitian ice sheets (Figure 2). These contained ~99% of the North American ice volume during the last glaciation, the remainder being in the Alpine glaciers of Alaska and the American Cordillera. The terms used (Figure 1) follow those in the last compilation of the glacial records of Canada (Fulton, 1989).

Early Glacial Initiation—MIS Substages 5b and 5d

A rapid increase in global ice volume occurred during MIS substage 5d. The initial growth of ice over North America probably first occurred on the broad uplands and mountains of the eastern Canadian Arctic, and possibly the central Canadian Arctic, at elevations above 400 m (Andrews and Mahaffy, 1976; Marshall, 2002). Computer simulations of three-dimensional glaciological models indicate that with greatly enhanced accumulation the rate of global sea level lowering during MIS substage 5d can be matched by initial growth of the ice sheet (Andrews and Mahaffy, 1976). All such models indicate that ice expands across Hudson Strait, coalescing from Baffin Island and Labrador and damming a lake in Hudson Bay (Adam, 1976). The lacustrine sediment below the Adams till in the Hudson Bay lowlands may have been deposited in such a lake (Fulton, 1989, p. 231).

However, it is unclear what changes in climatic conditions would drive such a dramatic increase in snow accumulation. One possibility is that there was early ice growth across the Canadian high Arctic islands and channels, thus terminating the outflow of cold, fresh Arctic waters from the Arctic Ocean into Baffin Bay. If this happened, then the modified Atlantic waters of the West Greenland Current could expand and fill the surface of Baffin Bay, resulting in more open water and increased snow accumulation over the long polar winters. However, firm ages for MIS substages 5a–5d events are lacking, and the chronology is based on stratigraphy, climate proxies, and amino acid racemization, which is dependent on both time and site temperature. Nevertheless, Baffin Island outlet glaciers seem to have extended to the present coastline soon after the Last Interglacial MIS substage 5e.

Insights into the onset of the last glaciation across the eastern Canadian Arctic come from the examination of marine sediments from the Labrador Sea, especially cores from the SW Greenland rise and Orphan Knoll (east of Newfoundland) (Hillaire-Marcel et al., 1994) (Figure 2). The chronology is based principally on the oxygen isotope stratigraphy of

Figure 1 Main Marine Isotope Stages (MIS) during the last glacial cycle and the variations in ice sheet history at various points around the main North American ice sheets and the timing of the major detrital carbonate (Heinrich events) in the Labrador Sea and Baffin Bay (see [Figure 2](#)).

Figure 2 Map of the outlines of the main North American Late Pleistocene ice sheets and mountain glacier complexes (the latter mainly in the western United States). IIS, Innuitian Ice Sheet. The locations of marine cores noted in the text are as follows: 1, core from the SW Greenland Rise; and 2, core on Orphan Knoll, off Newfoundland.

planktonic Foraminifera, radiocarbon dates for events ≤ 40 ka BP, and correlation with Heinrich events (Andrews, 1998; Bond et al., 1992). Substage 5e is noteworthy for the low $\delta^{18}\text{O}$ values and an absence of coarse ice-rafted sediments (ice rafted debris (IRD), $>125\ \mu\text{m}$). On the Greenland Rise, IRD increases during MIS substages 5b–5d to consistent but low values. At Orphan Knoll, the record does not extend back beyond MIS substage 5a but coarse sand (IRD) varies between 1 and 20% by weight, suggesting that icebergs were being released from Greenland and/or the Canadian Arctic.

Early Wisconsinan—MIS Stage 4

MIS 4 lies beyond the limits of radiocarbon dating but there seems to be general consensus that the decline in high-latitude Northern Hemisphere insolation at ca. 70–80 cal ka BP resulted in a major glacial interval across the high-latitude and high-altitude areas of North America (Clark and Lea, 1992). However, the chronological placement of early Wisconsinan glacial sediments is largely *ad hoc*, being based on their positions above a last interglacial deposit and below glacial or interstadial deposits of MIS 2 or 3. The last major compilation of Canadian Quaternary data (Fulton, 1989) indicated no clear certainty as to which glacial deposits fall within MIS 5 and 4, and our compilation of coeval events (Figure 1) is largely based on the premise of ‘least surprise.’ From British Columbia evidence of extensive MIS 4 glaciation has been reported (Clague and Ward, 2011). It appears reasonable, but not proven, that MIS 4 is represented by glacial sediments across most formerly glaciated regions of North America.

The general consensus in the literature is that there was a widespread and extensive MIS 4 glaciation across North America. If the initial glacial coverage during MIS 5 was limited to the uplands of the Canadian Arctic, then the move toward a full-fledged North American ice sheet must have been extremely dramatic because the interval between MIS substage 5a and the insolation trough of MIS 4 was only 12 000 years (Figure 1). This may indicate that the growth of the ice sheet was associated with more open-water conditions in the Labrador Sea and Baffin Bay, resulting in enhanced mass accumulations in order to account for the rapid decrease in global sea level. On Baffin Island, the faunas and sedimentology of large ice-proximal glacial marine deltas suggested that the Kogalu stade of assumed MIS 4 age was associated with relatively mild conditions, hence standing in contrast with the cold-based late Wisconsinan (MIS 2) glacial cover (Briner et al., 2003).

In the Labrador Sea, MIS 4 includes Heinrich event 6 (H-6) (Hillaire-Marcel et al., 1994) (Figure 1), the first of a series of massive carbonate and IRD events associated with the large ice stream extending along Hudson Strait, and possibly other ice streams extending into the Labrador Sea and Baffin Bay (Marshall and Clarke, 1996; Andrews et al., 1998). The assumption is that the ice sheet expanded from its areas of nucleation on the uplands of the northeastern Canadian Arctic and sub-Arctic and extended southwards; in doing so, a large fraction of the ice sheet extended across areas below sea level (as in the case today of the West Antarctic Ice Sheet). Many of these areas are floored by more easily eroded

Paleozoic carbonates, which may have had a major influence on the ice sheet thickness and dynamics (Fisher et al., 1985; Clark, 1994).

Middle Wisconsinan—MIS 3

The middle Wisconsinan extends from about the limits of radiocarbon dating to ca. 27 cal ka BP. It is a period of moderate insolation spanning between the insolation troughs of MIS 4 and 2 (Figure 1). Global sea level is poorly defined for this interval because of inherent problems in obtaining reliable numerical ages; thus, this interval has been difficult to understand because of the ambiguities of radiocarbon dates >30 cal ka BP. However, several of the massive sedimentary strata associated with the collapse of the Laurentide Ice Sheet (LIS), the Heinrich (H)-events, are dated within this interval, notably H-5, H-4, and H-3 (Andrews, 1998). These are prominent strata in sediments in the Labrador Sea (Hesse et al., 1997) and there may be coeval sediments within Baffin Bay, associated with the history of the large ice streams that fed into its northern end (Andrews, 1998; Dyke et al., 2002).

At the MIS 4/3 transition, rising insolation appears to have led to retreat of the LIS from the Canadian prairie provinces and from the Great Lakes region to deglaciation of the entire Cordilleran region from British Columbia to the Yukon and Alaska, and perhaps unexpectedly to substantial recession of glaciers in the High Arctic Islands. Interstadial deposits and redeposited fossils of MIS 3 age, including extinct megafaunal taxa, are widespread in these regions. Although a precise boundary of the remnant ice sheet is not known, ice appears to have been confined to the ‘hard bed’ of the Precambrian shield rocks (Andrews, 1987; Dyke et al., 2002). Massive iceberg discharges, possibly accompanied by subglacial outburst floods occurred in the vicinity of Hudson Strait, resulting in carbonate-rich sediments being dispersed from the Labrador Sea eastwards to the Portuguese and British continental margins. Heinrich events 6, 5, 4, and 3 all occur within the middle Wisconsinan MIS 3 and require a large ice sheet centered on Hudson Bay and draining through Hudson Strait to provide these ice-rafted and meltwater plume sediments.

During MIS 3, Baffin Bay also received discrete layers of detrital carbonate, principally dolomite from Paleozoic outcrops on the floors of channels that carried the major ice streams entering the north end of the bay from the Innuitian (Figure 1, INNUT. IS; Figure 2, IIS) and Greenland ice sheets (Andrews et al., 1998). Cosmogenic dates on moraines from east-central Baffin Island indicate that outlet glaciers terminated within the fiords and did not extend onto the continental shelf.

Late Wisconsinan—MIS 2/1

Globally, the maximum volume of ice sheets and glaciers since MIS substage 5e occurred close to the trough of Northern Hemisphere summer insolation during MIS 2 (Figure 1). Within this interval, radiocarbon dating is generally reliable. Although few details of the MIS 3/2 transition are known, it seems that ice sheets and glaciers expanded or regrew rapidly but not necessarily simultaneously. It was during this

transition that the Cordilleran and Innuitian ice sheets became reestablished, and the LIS expanded to limits that generally exceeded previous late Pleistocene, and in places all-time Pleistocene, limits (e.g. Jackson et al., 2011). These limits were reached in most places between 25 and 22 ^{14}C ka BP (27–25 cal ka BP) and maintained until approximately 18 ^{14}C ka BP (21.4 cal ka BP). Interesting exceptions are the southwestern Cordilleran Ice Sheet margin, which did not reach its maximum position until approximately 14.5 ^{14}C ka BP (17.3 cal ka BP), and the southeastern Innuitian Ice Sheet margin, which in places lingered near modern ice margins until 17–18 ^{14}C ka BP (Dyke et al., 2002).

Field evidence and theory have made it clear that bed topography and complex ice divide configurations inevitably lead to the flow within large ice sheets being organized into drainage basins (ice-flow basins?) centered on large ice streams (Marshall and Clarke, 1996). Heinrich events recorded in Labrador Sea indicate that the Hudson Strait ice stream was a, if not the, premier ice stream of the LIS, but also that its discharge behavior was highly erratic. Within the late Wisconsin, H-2 was approximately synchronous with the Last Glacial Maximum (LGM). Another massive event took place at ~16.5 cal ka BP (H-1), and H-0 is represented by an advance of ice from

Labrador across Hudson Strait approximately coeval with the Younger Dryas cold climatic event. In Baffin Bay, glacial activity in the High Arctic Channels is recorded by detrital carbonate events, of which the largest event occurred at approximately 14.5–15 cal ka BP and thus lagged behind H-1 (Figure 1).

By 1969, only a decade after the general advent of radiocarbon dating as a geologic tool, sufficient dates had been obtained to map the isochrons on the retreat of the North American ice sheets (Bryson et al., 1969; Prest, 1969). These data and interpretations were updated in 1987 and again more recently (Dyke and Prest, 1987; Dyke et al., 2002; Dyke, 2004). In the 35 years since the first compilations, there has been an enormous increase in the number of dates, but the overall pattern of retreat between ca. 22 and 6 cal ka BP has held remarkably constant (Figure 3). The overall retreat is strongly asymmetrical, with early and rapid retreat along southern, western, and northwestern margins, possibly associated with a combination of thin ice and calving into glacial lakes and seas (Andrews, 1973), and limited retreat along the eastern margin (Dyke, 2004) (Figure 3). However, the demise of the LIS was accompanied by the development of large glacial lakes in the Mackenzie, Hudson Bay, and St. Lawrence drainage basins and by the incursion of marine waters into Hudson

Figure 3 Isochrons on retreat of the Laurentide, Cordilleran, and Innuitian ice sheets. The dates are based on the radiocarbon (ka) timescale.

Bay via Hudson Strait. The final drainage of the glacial lakes through Hudson Strait occurred at ca. 8.2 cal ka BP (Barber et al., 1999; Clarke et al., 2004). This resulted in the final massive discharge of carbonate-rich sediments onto the Canadian eastern continental margin (Figure 1). The last marine-based portion of the LIS to become ice-free was Foxe Basin (ca. 7.5 cal ka BP), and during the past 7 cal ka BP the remnant of the LIS has retreated across Baffin Island but is 'preserved' in the basal ice of the Barnes Ice Cap.

Of particular interest to the paleoclimate community has been the export of freshwater from the margins of the LIS to the North Atlantic Ocean and attempts to link these outburst floods to specific Late Glacial climate events, such as during the Younger Dryas and 8.2 cal ka BP cold events (Barber et al., 1999; Clark et al., 2001; Clarke et al., 2003; Teller et al., 2005). However, despite decades of research on the chronology and routing of the various large glacial lakes, there is still considerable uncertainty concerning the precise timing of critical events (Teller et al., 2005), even though the links to resultant changes in the global thermohaline circulation appear probable.

New insights into the location of ice margins during late Wisconsinan (MIS 2) have come from the extensive application of cosmogenic exposure dating to areas of the Eastern Canadian Arctic, the High Canadian Arctic, the Canadian Rockies, and mountain glaciers in Alaska, Canada, and the continental United States. The application of this method has resulted in at least partial resolution of the 'Big Ice' versus 'Little Ice' controversy of the 1970s (Denton and Hughes, 1981). Specifically, evidence indicates that an Innuitian Ice Sheet merged with the Greenland Ice Sheet at the head of Baffin Bay and with the Laurentide Ice Sheet to the south (Dyke et al., 2002), that cold-based ice covered the forelands of eastern Baffin Island with retreat starting 12–13 cal ka BP, and that the Saglék Moraines of the Torngat Mountains (Clark et al., 2003) are post-LGM (i.e., Late Glacial) in age (~13 cal ka BP).

Late Pleistocene in South America

A Coronato and J Rabassa, Centro Austral de Investigaciones Científicas (CADIC-CONICET), Ushuaia, Argentina

© 2013 Elsevier B.V. All rights reserved.

Introduction

An updated review of the current state of the knowledge of late Pleistocene glaciations in South America, previously published in the first edition of this Encyclopedia (Coronato and Rabassa, 2007), is presented here. As this article is a revision of the previous work, only the contributions published during the last 5 years are discussed.

The glacial sequences of the Andean Cordillera are presented here separately for the Northern, Central, and Southern Andes.

The chronology of glacial advances has been refined in recent years, mostly through the use of different dating techniques, mainly cosmogenic radionuclides (^{10}Be , ^{26}Al) applied in several geographical areas such as the tropical Andes of Bolivia, the arid mountains of northern Chile and northwestern Argentina, Patagonia, the Magellan Straits, and Tierra del Fuego. In the Patagonian eastern side of the Andes, the occurrence of volcanic flows related to the different drifts favored the use of $^{39}\text{Ar}/^{40}\text{Ar}$ incremental heating dating technique as an option. Radiocarbon dating has also been undertaken on many lake-sediment cores and peat and organic sediments related to glacial deposits. In addition to advances in glacial chronology, precise regional mapping has improved and geomorphological knowledge has increased, mainly through the use of digital terrain models (DTMs) and satellite imagery as mapping tools. In addition, paleoseismic, stratigraphical, and sedimentological analyses have been undertaken on sediment cores from tropical and Patagonian lakes and fjords, which have contributed to the understanding of the late Pleistocene climate changes.

Detailed reviews of the Last Glacial Maximum (LGM) in Patagonia are given by Rabassa (2008), Coronato and Rabassa (2011), Martínez et al. (2011), and Rabassa et al. (2011), while detailed information on the glacial advances during the Wisconsinan Late Glacial and the Holocene in the Central Andes is presented by Rodbell et al. (2009).

Ice Advances in the Northern Andes (11° N–9° S, Higher Elevations at ~5000 masl)

Following the review by Coronato and Rabassa (2007), further advances in the late Pleistocene of the Northern Andes glaciations have been presented mainly by Mahaney et al. (2008) and Stansell et al. (2010).

In contrast to previous information, the regional equilibrium line altitude (ELA) depression during the LGM has been calculated in a range from 500 to 1625 m and a mean of $\sim 1200 \pm 300$ m (Lachniet and Vázquez-Selem, 2005). The wide range of elevation indicates that the ELA, as a paleoclimatic indicator of ice volume, should be analyzed and compared carefully, considering factors such as elevation, slope

orientation, insolation rate, and precipitation gradient. In the Eastern Mérida Andes of Venezuela (8° N–71° W), the early phases of the LGM are represented in a sequence of till, proglacial sediments, and peat and paleosols of the Pedregal sequence more than 40 m thick (Dierszowsky et al., 2005). The overlying sediments of the Pedregal Interstadial were dated at ca. 60 ka BP. Full-glacial and Late-glacial conditions returned between ~ 23 and 19 ka BP.

Late-glacial advances in the Venezuelan Andes were reported by Mahaney et al. (2008) based on geomorphology, sedimentology, and soil analyses on the glacial and glaciofluvial deposits that overlie older tills and peat beds. The authors proposed that ice had advanced ca. 12.4 cal ka BP in the Humboldt Massif and ca. 13.7–13.3 cal ka BP in catchments of the Eastern Cordillera. They correlated these advances with the Northern Hemisphere Younger Dryas cooling event. These discoveries were later confirmed by paleolimnological studies in the Mérida Andes by Stansell et al. (2010), who postulated that glaciers advanced at ca. 12.8 cal ka BP, reaching their maximum extent at ca. 12.6 cal ka BP. The ELA elevations were calculated by these authors between 360 and 480 masl, while the temperature was calculated as 2.2–2.9 °C colder than modern values. These authors also suggested that this Late-glacial advance reflects climate variations in good agreement with paleoclimatic records from marine sediment records of the Cariaco Basin.

A synthesis of new numerical ages presented here is shown in Figure 1.

Ice Advances in the Central Andes (9°–39° S, Higher Elevations at ~7000 masl)

The Central Andes is nowadays mainly affected by two systems of atmospheric circulation. While the north is influenced by the southeasterly South American Seasonal Monsoon (SASM) which brings humidity from Amazonia during the summer, the southern mountains receive rain from the Westerlies during the winter. This explains the climatic variability of the region, which had a major impact on glacier dynamics and landscape evolution. As a consequence, the debate about the interpretation of the information obtained from proxy records is still ongoing. According to Kull et al. (2008), several research groups have pointed out that an increase in summer precipitation occurred between 14 and 10 ka BP, forcing a Late-glacial ice advance in the western Altiplano, whereas the LGM was forced by a temperature decrease in the Eastern Cordillera at 16°–23° S. Moreover, pre- and post-LGM (32–14 ka BP) ice advances occurred at 30° S, related to increased precipitation and reduced temperature.

Millennial-scale climatic variations between 60 and 20 ka BP have been recognized in the tropical Andes in sediment

Figure 1 Distribution of the Andes Cordillera in South America and the influence of global atmosphere moist air movement. The ages constraining glacial and cold climatic periods are shown in the light blue boxes; they are differentiated by dating methods. The white lines in the boxes show that glacial advances have occurred through a weakly bracketed period. A question mark indicates where maximum ages are unknown.

cores from Lake Titicaca. Very distinctive sedimentary, geochemical, and paleobiological characteristics have allowed the recognition of wet regional climates. These events have been correlated to cold events recorded in the Greenland ice cores, indicating that near-global scale climate excursions controlled the increase of the SASM during the late Pleistocene (Fritz et al., 2010).

Glacial models of the northwestern Argentinian Andes (22°S) allowed Kull et al. (2008 and papers cited therein) to propose that a massive temperature fall of 4.5–8 °C, combined with a moderate precipitation increase, was required to force glaciers to expand during marine isotope stage (MIS) 2 (25–18 ka BP). This fact shows that the more humid slopes of the Andes were sensitive areas for glaciations during the LGM. This arose from temperature decrease, whereas on the more arid slopes, the glacier advances were forced by precipitation increase later during Wisconsinan Late-glacial times (Kull et al., 2008 and papers cited therein). The atmospheric

mechanisms resulting in humidity increase have been sought in a southward displacement of the Intertropical Convergence Zone (ITCZ) and the presence of La Niña climatic conditions (Zech et al., 2010).

In their regional synthesis, Zech et al. (2008) postulated that glaciers in the northern parts of the tropical Andes were temperature sensitive, while those located in the southern and western parts were precipitation sensitive. Little evidence of LGM ice advances has been found. These late cooling stages were found to be in phase with high Andean lake transgressions.

Clastic sediment flux analyses in alpine lakes in the tropical Andes have been used by Rodbell et al. (2009) as a proxy indicator for regional ice extent. They proposed that high clastic influx, triggered by increased precipitation, began before ~40 ka BP and culminated between 29 and 20 ka BP. This observation compares closely with the LGM in the high Bolivian and Peruvian valleys. Another regional clastic influx to the lakes

was between 16 and 12 ka BP, again corresponding to the Late-glacial period, in which several sets of moraine have been recorded in many valleys.

Pre-LGM (Before 25 ka BP)

Magnetic susceptibility analysis of radiocarbon-calibrated sediments from Lake Titicaca has suggested that the LGM began at ca. 60 ka BP, during the last part of MIS 4 in this region. Calcium carbonate and diatom-content records have suggested that the rise of lake level, probably reflecting precipitation increase, took place preceding glacial advances in the mountains (Fritz et al., 2010). In contrast to the results from the well-known Funza site (in the Northern Andes) where glacial climates were identified as cold and dry phases, these authors concluded that the glacial phases were cold and wet on the Bolivian Altiplano.

Likewise, further south, in the northern/central Chilean Andes, it has been argued that the most extensive glaciation occurred earlier than 32 ka, based on ^{10}Be surface-exposure dating and the degree of morainic erosion (Zech et al., 2011). Nevertheless, the scarcity of available geomorphological and cosmogenic exposure data does not allow the dating of the climatic deterioration which forced glaciers to grow.

Climatic conditions that were more humid during pre-LGM times than at present were determined from multidisciplinary lacustrine investigations of the Lake Tagua-Tagua basin (36° S, Chile), at the foot of the Andes (Valero-Garcés et al., 2005). High-stand levels, which occurred before 43.5 cal ka BP and particularly between 40 and 21.5 cal ka BP, were interpreted as resulting from precipitation increase in response to enhanced westerly wind activity. The available information supports Smith et al. (2005) who suggested that the local LGM might have occurred late in MIS 3, rather than close to 21 ka BP. Similar results were recently presented by Zech et al. (2011), who provided evidence that full-glacial conditions occurred ca. 39 ka BP in the southern Central Andes (Ruca Choroí valley, 39° S) and that further glacial advances did not occur there until the Late Glacial. Based on ^{10}Be boulder exposure ages on moraines, they suggested that increased precipitation arising from a northward shift of the Westerlies was the reason for glacier enlargement along the Central Andes, from northern Chile and Argentina (22° S) to around 39° S (middle Neuquén province, Argentina).

LGM (25–18 ka BP)

The LGM in the Cordillera Blanca (9° S–77° W, Peruvian Andes) was studied by Farber et al. (2005). They reported that the Rurec moraine includes boulders that yield surface-exposure ages of between ca. 20 and 30 ka BP and an average age of ca. 23.4 ka BP. They considered this moraine the indicator of the LGM limit in the Cordillera Blanca. However, cosmogenic ages of ca. 29 ka BP suggest that they represent the beginning of glacier advances from the Western Cordillera before the LGM developed fully.

A few valleys of the Cordillera Huayhuash (10° S, 76° W, ~4800 masl) in the Peruvian Andes preserve geomorphological evidence of glacial advances. ^{10}Be exposure surface ages and radiocarbon dating from peat bogs indicate that the LGM advance occurred there at 20–22 ka and before 26 ka

(Hall et al., 2009). This is consistent with the LGM chronology proposed by other authors in other regions of the tropical Andes. The similar geomorphological character and ^{10}Be surface-exposure dates of moraines in the middle and upper Peruvian Andes valleys allowed Smith et al. (2005) to conclude that LGM conditions were established in this region at ca. 32–21 ka BP.

Maximum glacial conditions were also studied using the ^{10}Be surface-exposure technique on morainic boulders from the Cordillera Real and the Cordillera Cochabamba by Zech et al. (2007). Their conclusions correspond closely with previous studies by Smith et al. (2005) and Farber et al. (2005), who also presented radiocarbon dates and lake-sediment analyses. These results indicate that maximum ice extent occurred ca. 22–25 ka BP. After testing a climatic model, Kull et al. (2008) concluded that a massive temperature depression of about 6.4 °C had allowed the glaciers to advance during this time.

Glacial deposits are well exposed in the filling of the Tarija–Padcaya basin, on the eastern side of the Bolivian Cordillera. Based on geomorphology, stratigraphy, and sedimentological analysis, Coltorti et al. (2010) reported MIS 4-age glacial landforms and deposits in this region for the first time. The sedimentary record in this basin ended at ca. 22 ka BP, but erosional glacial landforms present suggest that a major glacial advance occurred in the basin. This new evidence allowed these authors to hypothesize that glaciers flowed from the Bolivian Cordillera to the lower surrounding basins both during MIS 4 and 2.

In close correspondence with the Peruvian–Bolivian records previously presented by several authors, Zech et al. (2010) obtained results from ^{10}Be analyses of boulder exposure surfaces and radiocarbon dating of an 8-m sediment core from a glacial lake in the Sierras de Santa Victoria region (NW of Argentina, 22° S). Here, the LGM ice advance is represented by moraines dated older than 22.3 and 25.6 ka BP. These dates correlate with the lake-sediment records from the Uyuni Basin and Sajsi paleolake in Bolivia (Placzek et al., 2006). The glaciers' advance was forced by increased moisture advection onto the Altiplano (located to the west) resulting from the southward position of the ITCZ (Zech et al., 2010).

The Encierro (29° S) and Cordón Doña Rosa valleys (31° S), which are located along the 'Arid Diagonal' in Chile, were studied by Zech et al. (2008) who applied ^{10}Be exposure surface dating to morainic boulders. Here, the LGM advance could not be securely dated in both valleys because of the absence of prominent moraines and scarcity of boulders for dating or landscape instability and weathering. Further south, and also along the western slope of the Andes, the Laguna Tagua-Tagua (34° S, Chile) sediment core showed records that imply much higher precipitation during the full-glacial period compared to today, particularly during 40–21 cal year BP (Valero-Garcés et al., 2005), which could provide sufficient snow for glacier formation on the Andean summits during a global period of temperature decrease.

At almost the same latitude, but on the eastern slope of the Central Andes (36°–39° S, Neuquén, Argentina), glacial landforms and glaciofluvial deposits have been recognized between 1400 and 2900 masl and interpreted as LGM in age, although there are few numerical dates to confirm this. A detailed review of the alpine glacial advances during the late Pleistocene in this

region has been presented by Rabassa (2008) and Rabassa et al. (2011).

As at least two frontal moraine suites occur in several valleys of their eastern slopes, it is thought that lobes might have spread out from the volcanic peaks once or twice, but the detail remains uncertain. Cirques, hanging valleys, and frontal moraines can also be seen in the southern Central Andes, along the Chachil and Catan Lil ranges (500–2700 masl). Because of their elevation above the LGM equilibrium line (1500–2000 masl) and the low degree of erosion they display, they have been interpreted as belonging to the last glacial advance (Rabassa et al., 2011). Although detailed geomorphological and chronostratigraphic studies are required to support a glaciation model of this region of the Central Andes, it is thought that glaciers would have been shorter and thinner than those of the Southern Andes as a result of the lower availability of moisture from the Pacific Ocean.

Late Glacial (18–10 ka BP)

At the Cordillera Blanca (9° S) in the Peruvian Andes, boulder surface-exposure ages indicate that ice advances ranging from 18 to 16 ka BP with an average age of 16.6 ka BP occurred during the Wisconsin Late Glacial (Farber et al., 2005). They were interpreted as the second glacial advance during MIS 2, which retreated very quickly because no major moraine suites are preserved up the valley.

Geomorphological and sedimentary evidence in the high Central Peruvian Andean valleys show that Late-glacial advances occurred on both slopes of the Huayhuash Cordillera (10° S). Hall et al. (2009) found that glaciers advanced between 16 and 10 ka BP and postulated that temperature drop was the dominant control on glacier extent. These data corroborate the findings of Smith et al. (2005) from the Peruvian Andes, which indicated that glacial advances occurred between 20–15 and 14–12 ka BP.

At the Cordillera Cochabamba (17° S, Bolivia), glacial advances were recognized during the Heinrich Event 1 and Younger Dryas events by using ^{10}Be surface-exposure dating techniques. Zech et al. (2008) have obtained ^{10}Be exposure surface ages indicating that Late-glacial advances occurred at ca. 15 and 12 ka BP in the Cordillera Real and the Cordillera Cochabamba glaciers (16°–17° S). In addition, recent work has shown that the most extensive glaciation was recorded by exposure ages of 14.2 and 13.6 ka, while an inner lateral morainic arc was dated at 11.8–11.7 ka. The innermost moraine front yielded an exposure age of between 10.1 and 10.2 ka BP (Zech et al., 2010). This led these authors to propose that moisture advection, precipitation increase in the mountains, and glacial advances were forced by El Niño/Southern Oscillation (ENSO)-like conditions. Further south, on the northern slope of the Nevado Illimani (Cordillera Real, Bolivia), the age of glacial advances was also estimated by Smith et al. (2010) with the use of ^{10}Be cosmogenic nuclide surface dating. These authors found that glaciers retreated from moraines at 15.5–13.0 ka for the last time during the Late Glacial, suggesting that western-derived precipitation increased during this time, and a marked fluctuation has occurred in the east–west ELA gradient, located almost 500 m higher today.

At 22° S, in the Sierras de Santa Victoria (NW Argentina), glacier advances are known from boulder surface-exposure dating (^{10}Be) to have occurred at up to 14.5 and 13.8–12 ka BP (Zech et al., 2010). This coincides with lake transgression phases on the Altiplano, emphasizing the importance of precipitation for the positive ice mass balance in the arid regions of the Central Andes.

In the Encierro valley and the Cordón Doña Rosa (29°–30° S, Northern–Central Chile), boulder surface-exposure dating by ^{10}Be analyses performed on very prominent moraines indicates that extensive Late-glacial advances occurred ca. 14.7–11.6 ka BP (Zech et al., 2008). Further south, at Lago Tagua-Tagua (36° S), at the foot of the Andes, evidence of more humid climates was presented by Valero-Garcés et al. (2005). Here, humid intervals were detected in the lake-sediment record between 19.5–17 and 13.5–11.5 cal ka BP. Although no evidence of glacial landforms was related to these climatic models, they quite closely correspond to the younger group of moraines found in the Encierro valley and the Cordón Doña Rosa.

Eastward, along the Río Mendoza valley (2500 masl), close to the eastern slope of Mount Aconcagua (Figure 1), the ‘Horcones Drift,’ previously interpreted as pre-LGM glacial deposits, was reinterpreted as distal flows of rock avalanches by Fauqué et al. (2009). Based on the mineralogy, sedimentology, and cosmogenic radionuclide dating, these authors postulated that deposits at the bottom of the valley are remnants of megalandslides that occurred on the southern slope of Mount Aconcagua, rejecting their interpretation as moraine deposits. The landslides occurred upon the Horcones paleoglacier and the sediments were carried by the ice to their final deposition down valley when the ice melted, during the Late Glacial. This new interpretation changed the regional glacial model, as proposed by previous authors, and emphasized that ancient mass-wasting process products are much more frequent than previously thought.

New Late-glacial cosmogenic radionuclide dates were provided by Zech et al. (2010) in the Ruca Choroí valley, southern Central Andes (39° S). Based on ^{10}Be exposure ages on boulder ages of between 17.9 and 14.8 ka BP, they postulated that the glacier was still occupying the upper part of the valley during Late-glacial times, but that most of the valley had become ice free by ca. 15.5 ka BP. They also suggested that minor ice readvances have occurred only in the cirques, where one exposure age of ca. 12.2 ka BP was obtained. Although these are quite interesting conclusions, more statistically based mean ages are required to establish a robust chronology for this region.

A synthesis of the new numerical ages presented in this article is shown in Figure 1.

Ice Advances in the Southern Andes (39°–55° S, Higher Elevations at 2000 masl)

LGM

The LGM is represented by the Nahuel Huapi, Segunda Angostura, and Moat drifts in the Northern and Southern Patagonian and Fuegian Andes, respectively.

Detailed information concerning the LGM extent and chronology in the more than 20 transverse eastern Andean valleys from 39° to 52° S were presented by Rabassa (2008), Martínez

et al. (2011), and Coronato and Rabassa (2011). These authors agree that the LGM limit is represented by one or more morainic arcs located close to the eastern heads of the glacial lakes and the marine channels.

In the Northern Patagonian Andes (39° S), the eastern frontal limit of the LGM glaciers was blocked by the end of the Central Andes ranges and volcanic tablelands. In most cases, piedmont glaciers were formed when alpine glaciers joined outside the main valleys, at the foot of the ranges and tablelands. No numerical ages are available for the LGM chronology in this region because of the lack of suitable material for dating. It is accepted that the glaciation had occurred in phase with that in southern Patagonia, that is, ca. 25 cal ka (Coronato and Rabassa, 2011; Rabassa, 2008), and perhaps simultaneously on both slopes of the Andes.

Further south, in the valley of Lago Buenos Aires (46° S, Argentina), ^{10}Be and ^{26}Al surface-exposure ages on erratic boulders from moraines were obtained by Douglass et al. (2006). They suggested that the LGM occurred here between 22.7 and 19.9 ka BP, broadly corresponding to the proposed ages of 27–25 and 23–22 ka BP found in the Lago Pueyrredón valley (47° S) by Hein et al. (2010). This closely matches the Magellan Straits (53° S) chronology. In this latter area, the LGM limits have been dated by cosmogenic nuclides at 25 ka BP (Kaplan et al., 2008). This number is well corroborated with other cosmogenic and radiocarbon dating formerly published by different authors.

Glasser et al. (2011) mapped several moraine belts along the Lago San Martín glacial valley (49° S) and performed ^{10}Be cosmogenic exposure ages on boulders. The results indicate that the moraine suite enclosing the lake formed at 22.4 ka BP. This date agrees with that for the Fenix Moraines of the northern Lago Buenos Aires region and with the southern Río Blanco moraines in Lago Pueyrredón. In addition, exposure surface ages of ca. 34–37 ka BP for boulders from an eastward morainic belt indicate that the maximum extent of ice was reached earlier, demonstrating that this valley was less covered by ice during the LGM than previous studies had suggested.

The LGM age is still not well bracketed in Tierra del Fuego (53°–55° S), although geomorphological mapping has shown very conspicuous moraine belts along all the main and tributary valleys (Coronato and Rabassa, 2011). Recent work in the Lago Fagnano area (54° S) has shown that two moraine suites occur 10–20 km apart; here they were interpreted as two LGM positions before general deglaciation (Coronato et al., 2009). Although the outer moraine system has been dated by thermoluminescence (TL) to 25.7 ka BP, and outer glaciofluvial deposits were dated at 16.2 ka BP, these ages should be considered preliminary. Along the Beagle Channel (55° S), terminal moraines have been mapped, but an appropriate chronology is yet to be established here (Coronato and Rabassa, 2011). The end of the LGM cycle has been identified by several authors at ca. 17 ka BP.

Late Glacial

Several glacial readvances have been proposed for the Wisconsin Late Glacial in the Chilean Lake District in particular, and for the eastern side of the Southern Andes in general (Coronato and Rabassa, 2007; Rabassa, 2008). Along the northern and southern shores of major glacial lakes, frontal moraines that descend

beneath the lake waters are quite visible. They are always located westward from the LGM terminal moraines and at much lower elevations than those within the cirques. Based on the radiocarbon age of basal peat, cosmogenic dating, and seismic surveys, the moraines were interpreted to be younger than those located at the heads of the lakes. Seismic surveys allowed Waldmann et al. (2010) to identify additional, previously undescribed, buried moraine suites (Coronato et al., 2009).

It is accepted that southern Patagonia and Tierra del Fuego were affected by a climatic deterioration that occurred in phase with the Antarctic Cold Reversal (ACR), whereas the cooling would have occurred later in the Northern Patagonian Andes, much closer to the Northern Hemisphere Younger Dryas Chron.

Glacial advances that occurred in the Lago Buenos Aires basin after the LGM have been identified at 17, 15.8, and 14.4 ka BP by Douglass et al. (2006) using ^{10}Be exposure dating techniques on morainic boulders.

Further south, in the Lago San Martín valley (49° S), Late-glacial-age moraines dammed the lake arm named 'Brazo Maipú' and provide evidence of past high-standing lake levels. A single boulder on the inner moraine crest yielded a ^{10}Be age of 14.3 ka BP, which closely corresponds to the age of other boulders. Collectively, these boulders indicate the age of the innermost moraines formed along this valley.

On the western side of the southernmost Andes (Gran Campo Nevado and Sound Skyring region, 53° S, Chile), a slowdown of the fjord-glacier retreat was noted by Kilian et al. (2007) between 14 and 11 ka BP, which was followed by complete ice retreat. Although they are close to each other, evidence in these valleys does not reflect deglaciation and Late-glacial advances as much as in the Magellan Straits. This is probably due to the different mountain ice caps and the calving effect at the ice fronts.

Along the Lago Fagnano (54° S) and the Beagle Channel (55° S), minimum basal radiocarbon ages from peat bogs show that glaciers definitively receded from the main valleys between 14.6 and 10 ka BP, but a detailed chronology of recessional moraines is not yet available.

According to Douglass et al. (2006), the 14.4 ka BP advance clearly reflects the impact of the ACR instead of a YD influence, thus indicating asynchrony with the Northern Patagonian Andes and with the Northern and Central Andes during the Late Glacial. This is potentially a result of the northern limit of the Westerlies. New evidence confirming this was presented by Moreno et al. (2009) from the western side of the Southern Patagonian Andes (50° S), where evidence for glacier readvances and colder episodes was bracketed by radiocarbon dates of between 14.8 and 12.6 ka BP. On the contrary, at the same latitude but on the eastern side of the Andes, boulder surface-exposure ages of the outermost Late-glacial moraines of Lago Argentino suggested glacier advances toward the end of the Younger Dryas Chron (Ackert et al., 2008). These advances were attributed to higher precipitation rather than temperature decrease. The ^{10}Be and ^{36}Cl mean exposure age of 10.8 ka BP, found by these authors, is inconsistent with previous results from the area but coherent with higher precipitation and resulting lake high-stands reported for other northern regions of semiarid Patagonia following the severe drought of the ACR times.

A synthesis of new numerical ages presented in this article is shown in [Figure 1](#).

Final Remarks

Knowledge of late Pleistocene glaciations in South America has improved greatly over the last 20 years. However, the chronological scheme and the paleoclimatic interpretation are still far from complete, with much work still being needed in certain areas. For instance, the late Pleistocene glaciations in the Equatorial Andes and Northern Andes are still poorly constrained. Apart from sediment-core results from the highest lake in the Chorreras valley ([Rodbell et al., 2009](#)) and research results previous to 2007, no new information has been found in the recent literature.

It is very difficult to establish only one setting for late Pleistocene glaciations that would cover all the Andean latitudinal belt. This is because of the highly different summit elevations (from 7000 to 1000 masl) and broadly varying atmospheric conditions. For example, past glaciers should have responded to atmospheric changes arising from the SASM and ITCZ circulation patterns in the Central Andes, but depending upon the slope orientation of the mountains.

It is clear that in the southern Central Andes, as well as in the Patagonian Andes, the westerly winds have controlled the moisture supply for glacial ice accumulation, independent of mountain elevation.

Several core drilling projects performed in the Central and Southern Andes lakes have provided excellent information on glacial sediment and water discharge and allowed paleoclimatic reconstructions, suggesting that these paleolimnological techniques are perhaps the most promising methodology for the near future.

The extreme aridity of the Central Andes, together with the lack of contact between the ice and the Patagonian forest, are responsible for the scarcity of organic material appropriate for radiocarbon dating. In recent years and with increasing frequency, ^{10}Be and other cosmogenic isotope surface-exposure dating techniques have provided chronological information about glacier advances and retreats. However, sufficient field evidence is still lacking to provide an adequate framework to the available numerical dates. Likewise, methodological uncertainties of cosmogenic exposure dating techniques conspire against regional correlations in South America, where the intervals between ice advances in different regions seem to be shorter than the usual method errors.

Late-glacial advances occurred all along the Andes, mostly in two phases, the younger close to the ACR and YD cooling events, the older very close to 19–16 cal ka BP. These circumstances are particularly noted in the high Central Andes.

In the southern latitudes of South America (beyond 46° S), the atmospheric dynamics and glacial growth were influenced not only by the Westerlies but also by the Antarctic Frontal Zone. Late-glacial ice readvances after the general LGM deglaciation seem to have taken place under the control of the ACR. This suggests a different response of glacier advances during the Late-glacial period in the Northern–Central Andes in relation to the Southern Andes, and a precise, reliable chronology for both areas is still needed.

The discrepancies between the northern and southern Patagonian response to millennial-scale climatic variation and how these regions are in-phase with the ACR episode or to the Northern Hemisphere YD event is a current research topic. Somewhere between the Magellan Straits region and the Northern Patagonian Andes, there was a switch in atmospheric influence from one condition to the other, but its location is still unknown.

Much scientific work is still urgently required and many areas are still blank, but significant progress has been achieved recently and a breakthrough in the knowledge of South American glaciations is clearly achievable within the next decade, thanks to multiple, interdisciplinary efforts from Colombia to Cape Horn.

Neoglaciation in Europe

J A Matthews, Swansea University, Swansea, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

In Europe, the term neoglaciation tends to be used in two ways. First, it is used for the recrudescence or regrowth of glaciers in the mid-Holocene following partial or complete deglaciation in the early Holocene. Neoglaciation in this conventional sense tends to be viewed as a response to gradual (multimillennial) climatic deterioration after an early Holocene thermal maximum or 'climatic optimum.' Second, it is used with reference to shorter term, possibly abrupt, century- to millennial-scale glacier expansion episodes whenever they occurred within the Holocene. Usage has shifted toward this second model of neoglacial events, also known as 'Little Ice Age'-type events, as more evidence has come to light on early Holocene glacial activity, the complexity of Holocene glacier variations has become better known, and interest has grown in climate variability on century-to-millennial timescales. The methods used to reconstruct Holocene glacier variations in Europe, and the detailed evidence relating to neoglaciation that is now available, are reviewed here with particular reference to Scandinavia and the Alps.

Reconstructing Neoglaciation

A wide range of methods has been used to reconstruct and date neoglaciation in Europe. These can be classified into four main approaches: (1) historical and documentary evidence of glacier variations, (2) moraine-ridge stratigraphy and the dating of glacier expansion episodes, (3) dating glacier retreat phases using dendroglaciology and archaeoglaciology, and (4) reconstructing continuous records using glaciolacustrine and glaciofluvial stratigraphy. The principles and strengths and weaknesses of each approach are outlined in the following sections.

Historical and Documentary Evidence of Glacier Variations

Historical and documentary sources, which range from written accounts, etchings, paintings, and sketches to photographs, maps, and annual retreat measurements, provide the most accurate means of reconstructing the most recent glacier variations and may also be used for calibrating other methods. Such evidence has proved invaluable for building up a detailed record of glacier variations over the last ~500 years in the Alps and for shorter periods in many other glacierized areas of Europe, including Scandinavia and Iceland. This evidence is available, however, only for selected locations and recent centuries, and requires the application of high standards of historical analysis and data verification.

Moraine-Ridge Stratigraphy and the Dating of Glacier Expansion Episodes

For earlier in the Holocene, and/or in the absence of historical evidence, moraine-ridge stratigraphy has been the most widely used approach to the reconstruction of glacier variations.

Moraine-ridge sequences or moraine complexes characterize the marginal zones of many glaciers throughout Europe. In some places, the timing of the glacier advances that produced the moraines has been estimated by radiocarbon dating of buried organic material, by tephrochronology (especially in Iceland), or by the application of rock-surface exposure-age dating techniques, including lichenometric dating, terrestrial cosmogenic-nuclide dating (TCND), and Schmidt-hammer exposure-age dating (SHD).

This approach has been most successful where either (1) moraine ridges that are well separated horizontally and can be clearly identified or (2) where complex lateral moraine sequences formed by accretion or superimposition can be investigated in vertical sections. The latter situation is illustrated in [Figure 1](#), which shows the lateral moraine complex at Simonykees, a glacier in the Venediger massif of the Austrian Alps. Historically dated moraine ridges and calibrated radiocarbon dates are linked via peat, soil profiles, and associated pollen stratigraphy. Radiocarbon dates provide minimum limiting ages for the relatively old moraines, while the pollen profiles provide indirect evidence of the younger glacier variations based on the association between glacier advances, low values of arboreal pollen (AP), and high values of nonarboreal pollen (NAP, dominated by Gramineae), which is a characteristic feature of such proximal mires.

There are at least four limitations of the moraine-stratigraphic approach including, first, the evidence relates primarily to times of moraine deposition at the maxima of glacier advances or highstands. The approach sheds little light on the extent or timing of the intervening phases of glacier recession. Second, the likelihood that evidence will have been destroyed by more extensive later advances is high. This is a major limitation in southern Norway, where the 'Little Ice Age' glacier advance was normally the most extensive of the mid-to-late Holocene. Third, radiocarbon dates associated with wood, peat, and buried paleosols, may be characterized by large calibration or interpretive errors. In the case of well-developed buried paleosols, for example, large apparent mean residence times (AMRT) may lead to radiocarbon dates that are up to several thousand years older than the moraines that buried them. Fourth, organic material suitable for radiocarbon dating may be sparse or absent at high-altitude and high-latitude sites.

These problems have led to increasing use of rock-surface exposure-age techniques. Lichenometry has been very successful for dating 'Little Ice Age' recessional moraines but its effective temporal range does not extend beyond the last ~500 years. Despite limitations on the precision of the technique, recent applications of TCND have demonstrated potential in both Scandinavia and the Alps, especially in relation to early Holocene moraines dating from the Preboreal period and, possibly, the '8200 event.' After being limited for several decades to relative age dating, SHD has been developed recently in southern Norway as a calibrated-age dating technique. Under optimum conditions, SHD appears capable of dating

Figure 1 Moraine-stratigraphic evidence of Holocene glacier variations at Simonykees, Austrian Alps. Interrelationships between the moraine ridges are shown schematically; insets show the stratigraphic units (numbered 1–6) that are related to glacier advances, and the associated pollen diagram from the mire (R3) that lies distal to the historically dated seventeenth–nineteenth century lateral moraines; stars indicate calibrated radiocarbon dates (AD) from the mire. Adapted from Patzelt G and Bortenschlager S (1973) Die postglazialen Gletscher- und Klimaschwankungen in der Venedigergruppe (Hohe Tauern, Ostalpen). *Zeitschrift für Geomorphologie NF, Supplement Band 16*: 25–72.

with a higher level of precision than is currently available using TCND. This is demonstrated in Figure 2, which shows the 95% confidence intervals associated with the predicted ages of two pre-'Little Ice Age' moraine ridges according to SHD and TCND.

Dating Glacier Retreat Phases Using Dendroglaciology and Archaeoglaciology

Reconstruction of the duration and timing of phases of glacier recession, and the position of the glaciers when at their minimum extents, has been more difficult. Knowledge of these aspects is essential to gain a complete picture of Holocene glacier variations and hence neoglaciation. Unprecedented glacier retreat during the late twentieth and early twenty-first centuries has provided new evidence for a dendroglaciological approach to phases of reduced glacier extent in the Alps. This is based on the radiocarbon dating of pieces of wood exposed on glacier forelands. The setting indicates that trees grew up-valley of present glacier snouts and hence that the glaciers were

previously smaller than their present shrunken state. The age range of the wood samples also permits reconstruction of the duration of the main retreat phases for the whole Holocene and shows that the glaciers were smaller than today for much of the early to mid-Holocene. In some cases, *in situ* stumps enable a minimum extent of the glacier recession to be determined precisely. Up to 12 phases of reduced glacier extent have been defined using this approach in the Swiss Alps (Figure 3(a)).

A further important dimension of dendroglaciology is the establishment of tree-ring chronologies derived from the sub-fossil wood, which indicate climatic fluctuations that are correlated with glacier variations. As the proximity of the glacier to growing trees varies, the 'glacier climate' may accentuate and modify the climatic signal expressed in the tree rings. This approach has considerable potential for reconstructing high-resolution glacier variations.

Following the hot summer of 2003, reduction in size of the Schnidejoch ice field in the Swiss Alps uncovered over 100 archaeological artifacts (hunting gear, fur, leather, woollen

Figure 2 (a) Four Schmidt-hammer exposure-age dates (SHD) for bedrock (B1, B2) and boulder (M1, M2) samples associated with two moraine ridges (M1, M2) at Austanbotnbreen, Jotunheimen, Norway, derived from various calibration curves. (b) Three terrestrial cosmogenic-nuclide dates (TCND using ^{10}Be) for boulders associated with the same moraines. The 95% confidence intervals shown for each date are narrower for SHD, the more precise estimates of which are capable of rejecting an 8.2 ka age for the moraines. Gray bands indicate known southern Norwegian neoglacial events. Adapted from Matthews JA and Winkler S (2011) Schmidt-hammer exposure-age dating (SHD): Application to early Holocene moraines and a reappraisal of the reliability of terrestrial cosmogenic-nuclide dating (TCND) at Austanbotnbreen, Jotunheimen, Norway. *Boreas* 40: 256–270.

clothing, tools, shoe nails, and coins, which have been dated by radiocarbon dating and archaeological means (Figure 3(b)). The ages of the finds fall into four distinct clusters, which indicate periods when glacier retreat was sufficient to open a transalpine route connecting northern Italy to the northern Alps: namely, 4900–4450 cal years BP, 4100–3650 cal years BP, first to third century AD, and eighth to fifteenth century AD (the last corresponding with the Medieval Warm Period). The preservation of Neolithic leather indicates, moreover, more-or-less permanent ice cover at that site since ~4900 cal years BP. This date is quite close to that of the ‘Alpine Iceman’ or ‘Ötzi,’ the remains of which were found in a similarly remarkable state of preservation after the melting-out of glacier ice close to the border between Austria and Italy. Both sets of finds are consistent with the onset of Neoglaciation, in the conventional sense, at or before ~5300 cal years BP (the date of the iceman himself and his associated artifacts).

Reconstructing Continuous Records Using Glaciolacustrine and Glaciofluvial Stratigraphy

Whereas all the approaches derived from the glacier foreland depend on piecing together fragmentary evidence, two types of distal sedimentary sequences have the potential for reconstructing records that are both continuous and high resolution. This approach has been widely applied in Scandinavia. In the case of glacier-fed lakes, glacier history is reflected in the minerogenic content of the lacustrine sediments. Strategically

located lakes that are sufficiently distal from this sediment source, or the second or third lake in a chain of lakes, have been found particularly useful. Upstream lakes act as traps for coarse sediment, whereas lower lakes contain a record of variations in the deposition of suspended sediment. Consequently, glacier presence and relatively large glacier extent are recorded by various sedimentological indicators such as visible silt layers, varves, high X-ray density, low weight on ignition (organic content), high silt content, high magnetic susceptibility, and lithological variations.

An example of variations in a glaciolacustrine sediment core is shown in Figure 4. Twenty-three lithostratigraphic units are recognized, which fall broadly into a tripartite structure. Organic-rich sediments, dating from ~10 000 to 2000 cal years BP, are sandwiched between silt-rich minerogenic materials deposited when glaciers were relatively extensive. The sedimentological indicators record short-term variations in glacier size, such as the rapid glacier expansion around 8200 cal years BP, and a longer-term neoglaciation buildup of glaciers after ~2000 cal years BP. In this case, high calcium carbonate content is indicative of relatively small glaciers because the glaciers within this catchment are located on noncalcareous bedrock.

Similar indicators can be used in the context of glaciofluvial stream-bank mires, which are flooded episodically by melt-water when overbank deposition of suspended sediment occurs. The example in Figure 5 shows the lithostratigraphy in two such mires where glacier expansion episodes are recorded by predominantly silty minerogenic units. During episodes of

Bøvertunsvatnet cores 1 and 2, jotunheimen

Figure 6 Reconstructed Holocene glacier variations from sites on opposite sides of the Smørstabbtindan massif, Jotunheimen, Norway. (a) Variations of Bjørnbreen (based on the evidence shown in Figure 5); (b) named local neoglacial events (also shown as horizontal shaded bands); (c) the age of major and minor glacier maxima; and (d) variations of Leirbreen/Bøverbreen on the west side of the massif (based on the evidence shown in Figure 4). All dates are in calibrated radiocarbon years. Adapted from Matthews JA, et al. (2005) Holocene glacier history of Bjørnbreen and climatic reconstruction in central Jotunheimen, Norway, based on proximal glaciofluvial stream-bank mires. *Quaternary Science Reviews* 24: 67–90.

reduced glacier extent, peat accumulation proceeds with little interruption. Depending on availability, glaciolacustrine and glaciofluvial sites can provide alternative and complementary strategies. The main limitations of these approaches are (1) differentiating the glacial signal from possible flood layers and colluvial inputs (which are generally coarser in texture), and (2) in the case of glaciofluvial sites, the possibility of changing patterns of deposition and erosion over the mire surface associated with discharge variations, shifting stream patterns, and the infilling of depositional basins. These limitations can generally be minimized by not relying on single sites and by taking full account of the geomorphological setting of the sites.

Pattern and Timing of Neoglaciation

Application of the aforementioned approaches, often in combination, has produced evidence of Holocene glacier variations from several regions of Europe, which have been summarized by Grove (2004). Here, emphasis is given to two regions – southern Scandinavia and the Alps – where the evidence has permitted reconstruction of the pattern and timing of neoglaciation in greatest detail.

Scandinavia

A near-continuous record of Holocene glacier variations in the Smørstabbtindan massif of Jotunheimen, southern Norway, which has been reconstructed from the glaciolacustrine and glaciofluvial evidence presented in Figures 4 and 5, is summarized in Figure 6. The results of the two approaches agree in most respects, despite relating to different glaciers on opposite sides of the massif. Using the conventional definition, the onset of neoglaciation can be recognized at ~5700 cal years BP and at least seven local neoglacial events can be identified.

The pattern for the Smørstabbtindan massif, taking account of results from additional sites now available (Figure 7(a)), is compared with similar detailed reconstructions from three other subregions of southern Scandinavia in Figure 7(b)–7(d). The four records indicate a fluctuating buildup of glaciers after the onset of neoglaciation at ~6500–6000 cal years BP, which culminated in the ‘Little Ice Age’ maximum (around the mid-eighteenth century in southern Norway). There is also good agreement on the absence of glaciers for prolonged intervals during the early to mid-Holocene, especially around 7000 cal years BP. Differences between the subregions can be accounted for by differences in glacier size, geometry, and

Figure 7 Holocene glacier variations in southern Scandinavia. (a–d) Estimated glacier size variations relative to modern for four glacierized subregions of southern Norway, and the conventional onset of neoglaciation (horizontal shaded band): (a) Smørstabbtindan, Jotunheimen (S; Matthews and Dresser, 2008); (b) Jostedalssbreen area (J; Nesje et al., 2000, 2001); (c) Hardangerjøkulen (H; Dahl and Nesje, 1996); (d) Nordre Folgefonna (N; Bakke et al., 2005b,c); and (e) southern Norwegian synthesis (shaded horizontal bands are the regional neoglaciation maxima shown as horizontal bars). Adapted from Matthews JA and Dresser PQ (2008) Holocene glacier variation chronology of the Smørstabbtindan massif, Jotunheimen, southern Norway, and the recognition of century- to millennial-scale European Neoglaciation Events. *The Holocene* 18: 181–201.

location, as well as dating uncertainties and the existence or not of a residual ice sheet at the beginning of the Holocene. The completeness of these records justifies the recognition of 17 regional neoglaciation events in southern Norway (Figure 7(e)), each defined by at least one major glacier maximum at the subregional scale. Ten of these major glacier maxima have been detected in at least two subregional records. Minor maxima, which are of limited scale or based on limited evidence, have not been used in defining the regional events.

Alps

A similar compilation for the Central and Eastern Alps is shown in Figure 8(a)–8(f). Up to 11 neoglaciation events were recognized as early as the 1970s, based on moraine stratigraphy (Figure 8(a)). More recently, dendroglaciology has revealed a similar number of glacier recession phases in Austria (Figure 8(b)) and in Switzerland (Figure 8(c)). A complementary record of glacier activity based on median grain size from

Lake Silvaplana in the Upper Engadine subregion of the south-eastern Swiss Alps (Figure 8(d)) indicates glaciers of restricted size between about 10 600 and 3500 cal years BP. After the latter date, continuous deposition of varves, together with relatively small median grain sizes, reflects an increase in glaciogenic silt and clay associated with conventional neoglaciation. This record is in good agreement with radiocarbon-dated peat from the glacier foreland of Rutor Glacier in the Italian Alps, which indicates that this glacier was smaller than today from at least 10 200 to 5800 cal years BP.

The summary of length variations of Swiss glaciers (Figure 8(e)) implies that, although neoglaciation events became more frequent in the late Holocene, each was of similar extent to the 'Little Ice Age' maximum of ~AD 1850. The Alpine synthesis shown in Figure 8(f) recognizes 23 Alpine regional neoglaciation events based on the glacier maxima recognizable in one or more of the individual records, while taking additional account of the relatively accurate glacier chronology for Swiss glaciers over the last 3500 years.

Figure 8 Holocene glacier variations in the Central and Eastern Alps. (a) Phases of glacier expansion in the Austrian Alps (Patzelt and Bortenschlager, 1973); (b) phases of glacier recession (white) of Austrian glaciers (Nicolussi and Patzelt, 2000b); (c) glacier recession phases (white) in the Swiss Alps (Hormes et al., 2001; Joerin et al., 2006); (d) median grain size variation in Lake Silvaplana, Swiss Alps (Leemann and Niessen, 1994); (e) glacier length variations in the Swiss Alps (Maisch et al. in Tinner and Ammann, 2001); and (f) Alpine synthesis (shaded bands represent major maxima ± 50 or ± 100 years). Adapted from Matthews JA and Dresser PQ (2008) Holocene glacier variation chronology of the Smørstabbtindan massif, Jotunheimen, southern Norway, and the recognition of century- to millennial-scale European Neoglacial Events. *The Holocene* 18: 181–201.

Models of Neoglaciation and Geographical Variation in Glacier Behavior

The evidence suggests that the two current models of neoglaciation extant in Europe are both oversimplifications of reality. First, the conventional model of a distinct neoglacial period after a long, glacier-free mid-Holocene is only applicable at the broadest level of generalization. Second, the more recent model of a largely undifferentiated Holocene punctuated by numerous abrupt glacier expansion episodes of similar extent is equally difficult to verify when the evidence is scrutinized in detail. Alternatively, elements of both models seem to vary in their applicability to particular regional or subregional records, and particular glaciers buck the trend.

Throughout Europe, therefore, the spatial and temporal patterns of Holocene glacier variations require a new, hybrid model of neoglaciation to supercede both current models. Such a model, in which long- and short-term variations are recognized, the magnitude and frequency of century- to millennial-scale glacier variations vary through time, and regional and subregional differences can be accommodated, is suggested by Figures 7 and 8. In general, the early Holocene appears to have been characterized by relatively large glaciers and infrequent, high-magnitude neoglacial events. Neoglacial events remained infrequent during the mid-Holocene when neoglacial events were relatively few in number and glaciers tended to be small and melted away for some of the time. Following the onset of neoglaciation, the area glacierized

Figure 9 Variations in the annual net mass balance of Ålfotbreen, southern Norway (open circles), and the Sarennes Glacier, southeastern France, Western Alps, related to the North Atlantic Oscillation Index (thick line), AD 1960–2000. Bn, Net balance. Adapted from Nesje A and Dahl SO (2003) The ‘Little Ice Age’ – Only temperature? *The Holocene* 13: 139–145.

increased considerably and the frequency of neoglaciation events increased, culminating in the Little Ice Age.

Apparent differences between glacier behavior within and between Scandinavia and the Alps can be related to glacier size, geometry, and location in relation to atmospheric circulation patterns. According to the records from southern Norway, the shortest glacier-free interval (~7000–6000 cal years BP) is associated with the largest ice body, Jostedalsgreen (Figure 7(b)), while the relatively small glaciers of Smørstabbtindan, Jotunheimen, appear more sensitive to the abrupt ~8200 cal years BP event. This is likely to reflect the rapid response of small glaciers to short-term climatic variations. Another factor to be taken into account is the differential sensitivity of glacier variations to seasonal aspects of climate, especially winter precipitation and summer temperature. In southern Norway, the importance of winter precipitation (relative to summer temperature) in explaining recent frontal variations decreases with continentality from west to east. This is because the winter balance dominates the annual net balance on the maritime (western) glaciers. Differences in the pattern and timing of neoglaciation events between northern and southern Scandinavia are likely to reflect shifts in the position and strength of the North Atlantic westerlies and other changes in the general circulation of the atmosphere, including the frequency of blocking anticyclones.

Atmospheric circulation patterns also help to explain some of the differences in glacier behavior between Scandinavia and the Alps. This is illustrated by the relationship between the annual net balance of Ålfotbreen (southwestern Norway), the Sarennes Glacier (southwestern Alps), and the North Atlantic Oscillation (NAO) Index (Figure 9). The antiphase relationship between the net mass balance of the two glaciers contrasts with the positive correlation ($r = +0.77$) between the net balance of the Norwegian glacier and the NAO Index. This correlation is consistent with the dominant effect of the winter balance on this maritime glacier and reflects the association between positive-NAO-Index winters and above-normal precipitation in

Iceland and adjacent northwestern Europe (while below-normal precipitation is received throughout southern Europe and the Mediterranean).

European Neoglaciation Events and Climatic Forcing Factors

The extent to which it is possible currently to recognize a Europe-wide pattern of neoglaciation events, and their climatic implications, can be assessed with reference to Figure 10. Here, 13 continental scale, European Neoglaciation Events (Figure 10(c)) are identified as the areas of overlap between the previously defined Southern Norwegian (Figure 10(b)) and Alpine (Figure 10(a)) regional events. It can therefore be argued that, notwithstanding the existence of regional and sub-regional differences, a majority of the regional events extend throughout Europe.

One of the several potential climatic forcing factors that may contribute to synchronous European Neoglaciation Events is low solar irradiance, represented in Figure 10(d) by periods of above average residual $\Delta^{14}\text{C}$. These periods correlate strongly with above average drift-ice rafting in the North Atlantic, derived from stacked ocean cores (Figure 10(e)), and less strongly with Central European cold-humid phases defined on the basis of terrestrial paleoecological indicators of timberline depression. It is perhaps not surprising, given the dependence of glacier variations on both winter precipitation and summer temperatures, that there is only partial agreement between continental-scale neoglaciation events and low solar irradiance. Several recent studies in the Alps have, however, suggested stronger correlations at the regional scale.

The implication of these data is that variation in solar irradiance, which may be periodic in character, is an important driver of century- to millennial-scale glacier and climatic variability in Europe. At least three other forcing factors are probably involved in explaining either the general multimillennial pattern or the timing of particular neoglaciation events. These are,

Figure 10 European Neoglacial Events, regional neoglacial events and related records. (a) regional Alpine Neoglacial Events (from Figure 8(f)); (b) regional Southern Norwegian Neoglacial Events (from Figure 7(e)); (c) 16 European Neoglacial Events defined as periods of overlap between the regional events in (a) and (b); (d) periods of above average residual $\Delta^{14}\text{C}$ and hence low solar irradiance (Bond et al., 2001); (e) periods of above average drift-ice rafting in the North Atlantic (Bond et al., 2001) using Bond's numbering system for nine major Holocene ice-rafting events; and (f) cold-humid phases in Central Europe (CE-1 to CE-8) based on tree pollen and plant macrofossils (Haas et al., 1998). Adapted from Matthews JA and Dresser PQ (2008) Holocene glacier variation chronology of the Smørstabbtindan massif, Jotunheimen, southern Norway, and the recognition of century- to millennial-scale European Neoglacial Events. *The Holocene* 18: 181–201.

first, the well-known reduction in solar radiation of around 8% that has affected the Northern Hemisphere during the Holocene as a result of changes in the Earth's orbital parameters (Milankovitch forcing). This may account for much of the general increase in the magnitude and frequency of neoglacial events toward the present and also for a conventional mid-to-late Holocene neoglaciation where this occurs. Second, volcanic forcing may make an effective contribution to both the general trend and to the timing of particular neoglacial events. Temporal clustering of large volcanic eruptions that introduce significant quantities of volcanic aerosols into the upper atmosphere provides the potential mechanism in this case. The third forcing factor is ocean forcing by freshwater outburst events

into the North Atlantic and Arctic Oceans from the Laurentide Ice Sheet and the Baltic Ice Lake with concomitant effects on European climate. This factor was a potential influence on neoglacial events only prior to about 8000 cal years BP.

Conclusion

- (i) Historical and documentary evidence, moraine-ridge stratigraphy, dendroglaciology, archaeoglaciology, and evidence from distal glaciolacustrine and glaciofluvial sediments, have been combined to reconstruct and compare

detailed, continuous records of Holocene glacier variations from both northern and southern Europe.

- (ii) Records from southern Norway suggest a conventional onset of neoglaciation at 6500–6000 cal years BP. Before this, Jostedalbreen, the largest ice cap on mainland Europe, melted away. Subsequently, southern Norwegian glaciers reached their late Holocene maximum extent in the 'Little Ice Age.' In the Alps, many glaciers advanced to similar positions during expansion episodes at various times during the Holocene. Consequently, it is more difficult to define a conventional onset to neoglaciation in the Alps.
- (iii) Throughout Europe, a large number of neogacial events, defined as century- to millennial-scale glacier expansion episodes separated by phases of glacier recession, have been recognized. At least 13 European Neogacial Events, defined as century- to millennial-scale events that occurred in both southern Norway and the Alps, can be identified. A hybrid model of neoglaciation is therefore supported in which the magnitude and frequency of European Neogacial Events tend to increase through the late Holocene, but differences exist between glaciers at regional and sub-regional scales, which may be accounted for largely in terms of atmospheric circulation patterns.
- (iv) It is likely that the pattern and timing of Holocene glacier variations in Europe will eventually be explained by a combination of four climatic forcing factors. Milankovitch forcing potentially explains residual glaciers in the early Holocene following deglaciation, mid-Holocene glacier demise, conventional neoglaciation, and the late Holocene buildup of glaciers. Solar forcing appears to account for the tendency toward periodic neogacial events. These gradual and regular changes seem to have been moderated by volcanic forcing from injections of volcanic aerosols into the atmosphere, and by ocean forcing (before about 8000 cal years BP) triggered by freshwater outbursts into the North Atlantic and Arctic Oceans.

Neoglaciation in the American Cordilleras

S C Porter, University of Washington, Seattle, WA, USA

Concept of Neoglaciation

By the middle of the past century, glacial geologists working in the high mountains of western North America had recognized that moraines near the termini of glaciers, far upvalley from those of the last (Wisconsin) glaciation, represented small-scale fluctuations of postglacial climate. In the 1930s and 1940s, Francois Matthes of the US Geological Survey published reports concerning his studies in the Sierra Nevada of California and proposed that Sierran glaciers had disappeared at the end of the Wisconsin glaciation during a time of mild climate, but then were reborn and reached their greatest size after the end of the Pleistocene (Matthes, 1942) (Figures 1 and 2). Previously, it had been widely assumed that modern glaciers were merely shrunken remnants of former large valley glaciers and ice caps and that fresh-looking moraines beyond modern glacier termini were recessional drift bodies left behind as the remaining ice wasted away. Matthes recognized that the large coastal glaciers of Alaska and Canada, as well as large valley glaciers on high Cascade volcanoes, likely persisted throughout the mild postglacial interval, but he inferred that smaller cirque and valley glaciers in the Cascades, Rocky Mountains, and Sierra Nevada disappeared as the climate warmed in postglacial time. He supported his inference by calling attention to a study of Owens Lake, at the eastern foot of the Sierra. In this study, it was estimated that 4000 years were required for the salt content of the lake to reach its modern concentration following the lake's desiccation during a mild mid-postglacial interval and its subsequent regeneration as the climate became cooler and wetter. Matthes postulated that the rebirth of Owens Lake and the nearby Sierran glaciers were responses to the same pattern of postglacial climate change and that the modern Sierran glaciers, therefore, were, in all probability, somewhat less than 4000 years old.

Recognition of a 'Little Ice Age'

Matthes recognized two sets of young moraines fronting the Sierran glaciers. Those adjacent to the glaciers were unstable and typically ice cored, whereas those beyond were smaller, concentric, and stable. He surmised that the former were comparable to moraines in the Alps that formed in the nineteenth century, whereas the latter were several centuries old. Matthes concluded that glacier oscillations of the past few centuries had been among the greatest during the past 4000 years of renewed glacier activity and marked the culmination of a 'Little Ice Age,' a name that had been proposed by a 'clever journalist.'

In the six decades since Matthes published his Sierran studies, many additional glacial-geological investigations have clarified the sequence and chronology of Holocene glacier variations, both in the Sierra and throughout the world. The concept of a Little Ice Age is now widely accepted and the term has been formalized by capitalizing it. Nevertheless, its duration

and detailed character remain subjects of continuing debate. Although it is widely agreed that this interval was confined to the past millennium, some place its beginning in the seventeenth century, whereas others place it as early as the thirteenth century. Furthermore, accumulating evidence has shown that this interval did not always include the culminating advance or advances of the past 4000 years.

The Hypsithermal Interval

By the mid-nineteenth century, European pollen analysts had identified a series of pollen zones spanning Holocene time, which they designated zones IV–IX. Deevey and Flint (1957) recognized an interval (zones V–VIII) of generally mild climate within this series and named it the Hypsithermal interval. The Hypsithermal followed the cool climate of the earliest Holocene time (pollen zone IV = Preboreal) and preceded an interval of cool late Holocene climate (pollen zone IX = Subatlantic). The ages of the zonal boundaries are based on radiocarbon dating (Mangerud, 1982).

Definition of Neoglaciation

A middle to late Holocene interval marked by repeated episodes of glacier advance has been given various names (e.g., Hypothermal, Katathermal, Medithermal, and Neoglaciation). As a result of its increasing use in the North American Cordillera, Porter and Denton (1967) proposed to define Neoglaciation as 'the climatic episode characterized by rebirth and/or growth of glaciers following maximum shrinkage during the Hypsithermal interval.' They argued that the maximum shrinkage probably coincided with the maximum Hypsithermal warmth, which, based on evidence available to them, appeared to have occurred between ~8000 and 5000 years ago. Further, they called attention to pollen studies in western North America that implied a regionally nonsynchronous transition from Hypsithermal to post-Hypsithermal climate, implying that this boundary was latitudinally time transgressive rather than isochronous. They attempted to resolve this problem by defining Neoglaciation as a geological-climate unit (a unit that may lack isochronous boundaries) and suggested that evidence of the initial Neoglacial advance in a given area might fall at any time within the past five millennia. In other words, in some areas, the early part of Neoglaciation may overlap the later part of the Hypsithermal interval. The Little Ice Age constituted the youngest, and sometimes the only, recognized Neoglacial episode. At the time their initial paper was written, Porter and Denton documented a pre-Little Ice Age Neoglacial advance approximately 2800 ¹⁴C years ago. Subsequent work suggested a possible additional Neoglacial advance approximately 5000 ¹⁴C years ago (Denton and Karlén, 1973; Denton and Porter, 1970).

Establishing Neoglacial Chronologies

The establishment of a reliable chronology of Neoglaciation depends on accurate dating. Whereas in Europe and Iceland, historical data (e.g., written observations, geographic and topographic maps, paintings, sketches, lithographs, and photographs) that record the position of accessible glacier margins span hundreds of years, in the Western Hemisphere such records seldom extend back more than a century (Porter, 1981). For many inaccessible glaciers, historical records began only in

Figure 1 Francois Matthes (US Geological Survey) was the first to propose the concept of a Little Ice Age.

the era of aerial photography and satellite imaging. Therefore, geologists have had to rely substantially on several physical and biological dating methods to develop chronologies, and these have varying degrees of reliability.

Radiocarbon dates commonly provide only maximum or minimum limiting ages for alpine moraines and glacial drift. However, a stacked succession of moraines may include buried soil, peat, or wood that provides bracketing ages for successive moraines. Chronologies can also be developed by dating organic matter in lakes and bogs lying on, behind, or beyond a moraine. The temporal variation in atmospheric radiocarbon means that for Holocene radiocarbon dates to be useful for correlation they should be calibrated using standard calibration curves (Stuiver et al., 1998). Radiocarbon ages in this article are expressed in ^{14}C years BP and calibrated ages in ^{14}C cal years BP.

Dendrochronology has been used to date late Holocene deposits in northwestern North America where glaciers terminated in forested areas. The life span of most forest trees is generally less than a millennium, so tree-ring dating based on the oldest tree is mainly applicable for dating middle to late Little Ice Age moraines. Minimum ages for advances have been obtained by coring the oldest trees growing on moraines. Sources of potential error include uncertainty as to whether the oldest tree has been found, the time between moraine construction and germination of the first seedlings, and the time for a seedling to grow to the height at which the tree was cored. Although these factors may lead to underestimating the age of a morainal substrate, in most cases the error range probably is no more than a decade or two. In some circumstances, the culmination of a glacier advance may be determined by coring trees at the ice margin that were tilted but not killed and noting a marked change in the pattern of ring growth due to tree disturbance.

Lichenometry has been the most useful dating method in the Brooks Range and the Canadian Arctic. Because of the slow

Figure 2 Cirque moraines, like those pictured here near Mt. Whitney in the southern Sierra Nevada, led Matthes to envision a rebirth of glaciers in the middle Holocene following their disappearance at the end of the last glaciation.

growth rate of the ubiquitous species *Rhizocarpon geographicum* at high latitudes, the method is applicable to most of the Neoglacial records (albeit with substantial error ranges at the older end of the timescale). In lower latitude mountains (e.g., the Rockies and Cascades), growth rates are more rapid, permitting high-resolution dating for the past century or two, but the effective range of lichenometry is generally placed within the Little Ice Age. The method has proved less useful in South America, where long radiocarbon-controlled growth curves are difficult to construct.

Tephrochronology has been used in dating Neoglacial moraines on and downwind from active volcanoes (e.g., in southern Alaska, the Cascade Range, and the Andes). Holocene tephra layers have been dated by means of bracketing radiocarbon dates, and their presence or absence on and/or beneath moraines permits limiting ages to be assigned to glacier advances. In Mt. Rainier National Park, for example, Holocene tephras from eruptions of Mt. Rainier, Mt. St. Helens, and Mt. Mazama provide bracketing ages for Neoglacial moraines (Figure 3).

Cosmogenic isotopes (e.g., ^3He , ^{10}Be , ^{26}Al , and ^{36}Cl) are being widely used to obtain surface-exposure ages of alpine moraine boulders, especially those of the last glaciation. Although cosmogenic isotopes can also be used to date Neoglacial deposits, few such dates have been reported. A study on Mt. Rainier in the Cascade Range, however, points to a potential problem. A large Holocene volcanic mudflow deposit at ~ 1800 m altitude is ~ 5000 years old, according to ^{14}C dating of incorporated wood. However, large boulders at the surface have ^{36}Cl surface-exposure ages half as old. This discrepancy is apparently due to a thick and persistent snow cover during successive Neoglacial events that shielded the mudflow boulders and adjacent Neoglacial moraines from cosmic radiation

(Mt. Rainier has had post-Little Ice Age annual snowfall totals that exceed 30 m). Thus, only moraines minimally affected by Neoglacial snow cover are likely to provide reliable exposure ages.

Neoglacial Chronology of North and South America

Most chronologies of Neoglaciation in American mountain ranges focus on selected areas, ranging from Alaska's Brooks Range to the southern Andes. Only the most important are reviewed here. In low latitudes, where the snow line is very high, modern glaciers and their Neoglacial predecessors terminated on land and were confined to high cirques and valley heads, mostly well above 4000 m. In middle latitudes, small valley and cirque glaciers lay at altitudes of 3000–4000 m, with the largest glaciers typically heading on high stratovolcanoes. At higher southern latitudes, many outlet glaciers of the large North and South Patagonian ice caps terminated in lake basins or in tidewater and experienced advance/retreat cycles like those of tidewater glaciers in southcoastal Alaska.

Brooks Range

Numerous cirque glaciers and small valley glaciers are located in the highest sectors of the Brooks Range. All lie above or beyond the treeline in a landscape of herbaceous tundra vegetation. Although radiocarbon dates have been obtained for some middle to late Neoglacial moraines, the glacial chronology is based mainly on lichenometric data obtained near the margin of 97 glaciers, mostly in the central part of the range (Calkin, 1988). A lichen growth curve that is controlled by radiocarbon dates back to 1300 years BP was extrapolated

Figure 3 Neoglacial moraines of Paradise Glacier (out of view to left) on Mt. Rainier volcano in the Cascade Range that are dated by tephrochronology. Tephra layers W (450 years), C (2200 years), Y (3400 years), and O (Mazama, 6800 years) are used to bracket the age of moraines. A grassy slope beyond the moraines is mantled by the entire suite of layers, demonstrating that it has not been covered by glacier ice since at least 6800 years ago. The two outer moraines are less than 3400 years old and more than 2200 years old, whereas the next moraine is less than 2200 and more than 450 years old. The innermost (late Little Ice Age) moraine is younger than 450 years.

linearly to 8000 years BP, thus spanning all of Neoglaciation. The estimated error range of the dates is $\pm 20\%$ (i.e., ± 1000 years for the earliest Neoglacial time). Moraines postdating 5000 years BP tend to be closely nested and often lie within less than 100 m of glacier margins (Figure 4). Early Neoglacial moraines (4200–4600 and 3400–3700 years old) have been found in the west-central Brooks Range. Pre-Little Ice Age Neoglacial moraines (~ 2700 –2900, 2200–2500, and 1600–2000 years old), as well as clusters averaging 1400–1600 and 1000–1300 years, are prominent in the central and eastern sectors of the range. Little Ice Age moraines that border nearly every glacier terminus have ages that cluster prominently at 600–900, 300–500, and 90 years BP.

Southern Alaska and Yukon Territory

This most extensively glacierized sector of the Americas includes thousands of small to large land-terminating glaciers, as well as numerous large tidewater-calving glaciers. Local Holocene chronologies are based mainly on radiocarbon and tree-ring dating. In the Kenai Mountains and other ranges that border the Gulf of Alaska, land-terminating glaciers experienced major periods of expansion during the Little Ice Age in the middle thirteenth, early fifteenth, middle seventeenth, and last half of the nineteenth centuries; earlier, pre-Little Ice Age advances are dated between approximately 1550 and 1300 years BP (Calkin et al., 2001; Wiles et al., 1999).

Figure 4 Moraines of a cirque glacier in the Brooks Range that border the ice margin have been dated by lichenometry. Using a growth curve extrapolated beyond 1300 years, the diameter (in mm) of the largest *Rhizocarpon geographicum* growing on each moraine provides an approximate age for a Neoglacial advance. Adapted from Ellis JM and Calkin PE (1984) Chronology of Holocene glaciation, central Brooks Range, Alaska. *Geological Society of America Bulletin* 95: 897–912, Figure 9B.

By contrast, large calving tidewater glaciers in this region experience advance/retreat cycles that differ from glacier to glacier: some glaciers may be advancing while others are retreating or are stabilized. Nevertheless, on the scale of millennia, a gross correspondence can be seen among phases of expansion, which may last nearly 1000 years, and intervals of rapid retreat (Calkin et al., 2001; Figure 5). The record of calving glacier activity has mainly been reconstructed from wood- and peat-bearing deposits exposed by ice recession (Wiles et al., 1999). Rooted tree stumps, sheared off by advancing ice, have been used to develop ring chronologies that help assess the rate of glacier advance and time of glacier maxima. Around the Gulf of Alaska, Neoglacial episodes of calving glacier expansion may have begun as early as 4500 years BP in Glacier Bay and ~ 3600 –3000 years BP and 1300–1400 years BP for other coastal glaciers. A major episode of advance coincided with the Little Ice Age (Figure 5). By the end of the nineteenth century, many of these large calving glaciers were at or near their Little Ice Age maxima, but within several decades they had begun to retreat. By the end of the twentieth century, most had receded to fjord heads and their termini were either stabilized or once again advancing. Columbia Glacier was the last of the major calving glaciers to begin retreating and its terminus is now receding rapidly upfjord.

Neoglacial advances in the northeastern St. Elias Mountains of Yukon Territory culminated ~ 2800 , 2600, and 1230–1050 years BP and were followed by Little Ice Age advances (Denton and Karlén, 1977). The Kaskawulsh Glacier was advancing 500 years BP and subsequently attained its greatest extent of the past ca. 10 000 years.

Figure 5 A record showing that intervals of advance for calving and land-terminating glaciers in southcoastal Alaska span the past two millennia. For tidewater glaciers, intervals of advance vary widely but nevertheless group very broadly in two intervals centered on ~ 500 and 1500 years ago (Little Ice Age and pre-Little Ice Age). Land-terminating advances fall mostly in the fifteenth to nineteenth centuries, but three glaciers also advanced close to 1500 years ago. Adapted from Calkin PE, Wiles GC, and Barclay DJ (2001) Holocene coastal glaciation of Alaska. *Quaternary Science Reviews* 20: 449–461, Figure 2.

Coast Mountains of British Columbia

In the southern Coast Mountains of British Columbia, the earliest advance is dated from glacially overridden tree stumps in growth position at Garibaldi Park (~5300 years BP). The apparent absence of moraines of this age implies that this early advance was less extensive than later ones. In the northern Coast Mountains, a middle Neoglacial advance that culminated ~2300 years BP was equal to or more extensive than Little Ice Age advances, whereas an advance ~1900 years BP was as extensive. The Little Ice Age glacier expansion began shortly before 900 years BP and culminated in the eighteenth or nineteenth century when most glacier termini reached their maximum Neoglacial limit (Osborn and Luckman, 1988; Ryder and Thomson, 1986).

Cascade Range

Many of the hundreds of glaciers in the Cascade Range terminate in vegetated terrain where radiocarbon dating of buried wood and soils, lichenometry, and tree-ring dating are feasible methods for dating Neoglacial deposits. Tephrochronology is also applicable, and in a few cases historical data extend back to the middle to late nineteenth century. An early advance (~4700–4900 years BP) is inferred from *in situ* glacier-sheared trees that were exposed by the recent retreat of the South Cascade Glacier (Miller, 1969). No moraines of this advance have been identified beyond the Little Ice Age moraines, implying that this advance was less extensive than those of recent centuries. Ring counts show that a tree growing on a nearby Chickamin Glacier moraine germinated before AD 1280; this moraine may record the onset of the Little Ice Age in the northern Cascades. Most Neoglacial Cascade moraines date to the sixteenth, nineteenth, and twentieth centuries. Tephra layers broadly bracket earlier Neoglacial moraines at Mt. Rainier between 3400 and 2200 years ago and 2200 and 450 years ago (Crandell and Miller, 1965; Figure 3). At Nisqually Glacier, a 3400-year-old tephra is found immediately adjacent to the outermost Little Ice Age moraine, which marks the most extensive Neoglacial advance (ca. AD 1825).

Canadian and US Rocky Mountains

No direct evidence of Neoglacial glacier advances older than 4500 years BP has been reported from the Canadian Rockies. Evidence of advances from 4400 to 3000 and from 2300 to 1800 years BP has been found at Bugaboo Glacier in the Purcell Mountains (Osborn and Luckman, 1988). Little Ice Age advances, dated by tree-ring records, began soon after 900 years BP and culminated mainly in the eighteenth or nineteenth century (Luckman, 1993); for most investigated glaciers, these were the most extensive Holocene advances in the Canadian Rockies.

Because of a paucity of radiocarbon dates, the Neoglacial chronology of the US Rocky Mountains relies mainly on lichenometry and an array of relative dating methods (e.g., soils and relative rock-weathering rates) that are useful in distinguishing presumed Neoglacial cirque moraines and rock glaciers from early Holocene or late-glacial deposits (Burke and Birkeland, 1983). The youngest deposits are assigned to the Little Ice Age.

Rock glacier lobes in the central Colorado Rockies dated by lichenometry have ages that cluster at ~3100, 2100, and 1200 cal years ago. In the San Juan Mountains of the southern Rockies, where Neoglacial moraines are lacking, many cirques have been ice free for at least 14 000 years.

Sierra Nevada

Although the Sierra Nevada might well be considered the 'classic' area of the Little Ice Age and Neoglaciation, its geological record of Holocene glaciation is sparse, not yet well studied, and rather poorly dated (Clark and Gillespie, 1997). The known moraine record is confined mainly to the Little Ice Age, although cores from the Conness Lakes taken downvalley from cirque moraines suggest that Neoglacial glacier activity may have begun by ~3200 years BP (Konrad and Clark, 1998; i.e., remarkably close to Matthes' original estimate). Moraines of the Little Ice Age are, appropriately, referred to as Matthes-age moraines; on the basis of lichenometry, radiocarbon dating, and tephrochronology, they date to the past ~700 years. Lichen ages of ~970 and 1100 years BP for moraines in the east-central Sierra were reported more than three decades ago, but they have not been confirmed or replicated elsewhere in the range.

Northern and Central Andes

Moraines built during the early and middle phases of Neoglaciation in the northern Andes of Colombia and Ecuador are yet to be identified and dated. In Colombia, Little Ice Age advances are inferred to have overridden and buried any older Holocene moraines. The available evidence suggests that the maximum Neoglacial advances occurred in the sixteenth and seventeenth centuries.

Numerous studies of Neoglacial deposits in the lofty tropical to subtropical Peruvian Andes suggest a somewhat abbreviated record of ice advances (Clapperton, 1993). Some studies are contradictory. For example, in the Cordillera Blanca and Cordillera de Raura, glaciers apparently were in advanced positions ~4300 and soon after 2400 years ago, whereas in the Cordillera Vilcanota/Quelcaya area, radiocarbon dates of organic matter between superposed moraines imply no glacier advances between ~10 000 and 3000 years ago. Most dated moraines in this sector of the Andes have only minimum or maximum ages that may not be closely limiting. Ubiquitous Little Ice Age moraines beyond existing glaciers are as old as 600 years.

Southern Andes

Moraines of the southern Andes that predate the Little Ice Age have been dated mainly by radiocarbon analysis of *in situ* or glacier-transported trees in superposed moraine sequences and of basal peat in bogs on moraines or in meltwater channels. Tree-ring chronologies have been developed for some Little Ice Age moraine sequences.

Middle to late Holocene moraines beyond large outlet glaciers of the Northern and Southern Patagonian ice caps fall into several distinct groups based on limiting radiocarbon ages (Clapperton, 1993; Mercer, 1976). An early Neoglacial

advance between 4700 and 4200 years BP was the most extensive for many maritime glaciers, but glaciers to the east were generally less extensive during this early advance phase than during a subsequent middle Neoglacial interval between 2700 and 2000 years ago. Little Ice Age moraines are found at all the glaciers investigated and fall within the range of 900–100 years BP.

A majority of available dates provide only minimum limiting ages, and the assumption commonly made is that these ages are closely limiting. However, some dates give only broad age brackets (e.g., sometime within a 1500-year interval or sometime after ~3300 years ago), making close age assignment and reliable correlations impossible. Moraines deposited by tidewater- or lake-calving glaciers may be out of phase with the regional pattern, as is the case with such glaciers in coastal Alaska.

Onset of Neoglaciation

Evidence bearing on the initial advance of glaciers during Neoglaciation is most abundant in the middle southern latitudes (i.e., southern Andes and New Zealand Alps; Porter, 2000). Limiting and bracketing ages of the earliest Neoglacial moraines in the southern Andes point to advances that culminated ~4600–4400 years ago (5400–4900 cal years ago) (Figure 6). Only in the Brooks Range have cirque moraines approaching this age been reported in North America. The Cascades of Washington and British Columbia and Glacier Bay, Alaska, are the only sites in North America where glacially overridden evidence of such early advances is known. It seems likely that glaciers in other regions of the cordillera north of the southern Andes also experienced early glacier activity at that time, but the evidence likely has been obscured by later, more extensive advances.

Temporal Pattern of Glacier Variations

Dates for Neoglacial advances tend to cluster broadly in three time intervals (Figure 7). The youngest (late Neoglaciation) includes the Little Ice Age (~800–100 years ago), which is prominent in most glacial records along the American cordilleras. An earlier event (pre-Little Ice Age, ~1500–1100 years ago) is represented by glacier advances in the Brooks Range, coastal Alaska and British Columbia, Yukon Territory, and possibly the Cascades and Sierra Nevada. Middle Neoglacial events (~3300–2700 and 2400–2000 years ago) are recorded in the Brooks Range, southcoastal Alaska, Yukon Territory, the Canadian and US Rocky Mountains, and likely in the Cascades and Sierra Nevada. Evidence of early Neoglacial activity (4800–4100 years ago) is found in the Brooks Range, coastal Alaska, Canadian Rockies, Cascades, and central Andes. The disparate nature of most Neoglacial records reflects limited research on and dating of pre-Little Ice Age moraine sequences, as well as the obliteration or burial of earlier deposits during Little Ice Age advances. An exception is the Brooks Range, where cold, slow-moving cirque glaciers produced nested and superposed moraines that occasionally include early Neoglacial deposits.

Figure 6 The onset of Neoglaciation in the southern Andes is recorded by maximum, minimum, and approximate ages for advances of 11 glaciers that narrow an initial expansion to the interval of ~4600–4400 years BP (5400–4900 cal years BP). Adapted from Porter SC (2000) Onset of Neoglaciation in the Southern Hemisphere. *Journal of Quaternary Science* 15: 395–408, Figure 5.

Figure 7 Plot of dates related to Neoglacial events (shaded intervals) recorded along the North and South American cordilleras.

The timing of quasicyclic Neoglacial glacier variations on millennial timescales has been attributed to variations in solar output (Denton and Karlén, 1973). On decadal and shorter scales, however, glaciers may respond to large explosive volcanic eruptions that affect climate and glacier mass balance on a hemispheric or global scale (Porter, 1986). In addition, calving dynamics can affect the advance/retreat pattern of tidewater and lacustrine glacier termini.

Figure 8 Moraine records of cirque and valley glaciers. (a) Neoglacial moraine succession of a small cirque glacier in which the oldest moraine (EN, early Neoglacial) has acted as a barrier to the glacier during later advances. Advancing ice may run up against older moraine barriers, developing a stacked sequence, and it may override them, burying the older deposits. MN, middle Neoglacial; LN, late Neoglacial; LIA, Little Ice Age. (b) Successively more extensive advances of a valley glacier override earlier moraines (dashed lines) along the valley floor, with the Little Ice Age advance being the greatest of Neoglacial. Evidence of earlier advances is preserved in lateral-moraine stratigraphy in which buried soils (p) separate deposits of successive advances.

Hemispheric Contrasts in Relative Glacier Extent

The pattern of relative glacier extent during Neoglacial episodes varies with latitude along the Americas. In the central and southern Andes, valley glaciers reached their greatest extent during early Neoglacial time, with successive subsequent limits diminishing in extent. In the Cascades, the oldest moraines date to middle Neoglacial, although limited evidence indicates more restricted early Neoglacial activity. Farther north, Little Ice Age moraines represent the most extensive advances. The limited older record in the Brooks Range may reflect occasional preservation near the margin of stacked and closely nested moraine sequences (Figures 4 and 8).

This latitudinal variation in relative glacier extent is likely related to the hemispheric contrast in insolation (incident solar radiation). In southern South America, summer insolation (and summer temperature) was lowest at the onset of Neoglacial, when glaciers reached their maximum limits, but it became progressively higher approaching the Little Ice Age when glaciers were smaller (Figure 9). By contrast, in the Northern Hemisphere, insolation was initially high during early Neoglacial and fell toward the Little Ice Age. The maximum Neoglacial ice extent would be predicted to occur during the Little Ice Age, which is generally the case.

Figure 9 Relative extents of Neoglacial moraines in the North and South American cordilleras compared with the summer insolation received at different latitudes. In northern North America, insolation was lowest and glaciers were most extensive during late Neoglacial time. Early Neoglacial records are rarely found, all but a very few having been overridden by middle and late Neoglacial advances, which were often of nearly equal extent. In southern South America, glaciers were most extensive early in Neoglacial when insolation was lowest, and their limits shrank as insolation increased toward the Little Ice Age.

Introduction

Cores through the polar ice sheets provide a remarkable record of past environmental conditions, on timescales of thousands of millennia to the last few decades. Ice-core records are unique in paleoclimatology, primarily because of the very high ice accumulation rates (providing excellent time resolution), the preservation of multiple proxies of past environmental conditions, and the fact that small samples of the ancient atmosphere are entombed in bubbles.

Ice coring evolved as a science in the 1950s and 1960s through the pioneering efforts of scientists from several nations and is now conducted by a variety of national and international research teams, in the Arctic, Antarctic, and glaciated mountain regions of the world. Existing ice-core data inform us about human impacts on the polar regions and the global atmosphere as well as the long march of glacial–interglacial climate changes over the last 800 000 years; they also provide spectacular, if only partly understood, data about abrupt climate change during the last Ice Age and the stability of climate over the last 10 000 years. Future ice cores will take the records further back in time and also provide more detailed spatiotemporal information about the evolution of climate and environmental change. Summaries of a number of specific areas of ice-core research are available elsewhere in this encyclopedia.

Ice-Core Basics

Snow accumulates on the polar plateaus of Antarctica and Greenland, and at high elevations in lower latitude mountain regions, in a regularly ordered fashion that preserves a stratigraphic sequence accessible by drilling vertical borings in the ice. Collecting these cores is a specialized engineering challenge. The drilling equipment used for ice coring was developed in the late 1950s and early 1960s, and has since been continuously improved upon. Because ice is a deformable material and flows, ice-coring locations must be chosen carefully to extract the most reliable paleoclimate information. The best drilling sites are generally on or near ice divides ([Figure 1](#)), where ice deposited at or near the same elevation as the current surface elevation can be obtained, and the distortion of the age versus depth curve due to thinning can be reliably modeled.

Ice cores of various lengths are collected for different purposes. Shallow cores (generally <100–200 m) can be collected relatively easily with lightweight equipment and generally cover a few hundred years of history, depending on accumulation rates. Networks of shallow cores have been collected to study spatial variations in climate on these timescales (e.g., the Program for Arctic Regional Climate Assessment (PARCA) and International Trans-Antarctic Scientific Expedition (ITASE) programs in Greenland and Antarctica, respectively). Deeper cores require larger equipment and fluid-filled boreholes to avoid collapse of the hole. Drilling fluids are typically petroleum-derived fluids such as refined kerosene, but other organic liquids (e.g., butyl acetate) have also been used. The physical characteristics of the fluid, particularly freezing point and viscosity (and viscosity–temperature characteristics), are critical parameters and can make the choice of appropriate fluids a challenge. The fluid-filled hole also provides access for measuring ice sheet temperature profiles, which are useful for paleothermometry. The deepest cores (>3000 m) in Greenland and Antarctica have been collected during multiyear campaigns from temporary or permanent scientific camps.

Perhaps the most unique aspect of ice cores is that they trap ancient atmosphere when surface snowfall compacts to ice. This happens at the base of the firm, or unconsolidated snow layer, typically 50–100 m below the surface in polar regions, and shallower at high accumulation sites with warmer temperatures.

Ice-Core Chronology

Accurate chronology is obviously key to using ice-core records to study past environmental changes, particularly to compare features of ice-core records with data from other locations. Annual layer counting is the most powerful and best known technique, but a variety of other methods are also employed.

Layer counting provides the most accurate dating. Annual layering can be discerned visually because of seasonal variations in snow properties ([Figure 2](#)), but annual signals are also present in a variety of geochemical parameters, including stable isotopes, electrical conductivity, and a variety of soluble chemical species. Recent work uses several of these parameters at the same time to construct chronologies.

Annual layers are not discernable at all sites, and thinning makes them difficult to discern in older sections of deep ice

Figure 1 Schematic cross-section of an ice sheet. Ideal ice-core drilling sites are at or near the 'ice divide' at the center of the ice sheet where a core recovers ice deposited at approximately the same location on the surface.

Figure 2 Annual layers in the GISP2 ice core. This section of ice core is ~30 cm long. The horizontal line is the edge of a plastic sample tray.

cores. In many cases, other techniques are needed to establish the ages of deep ice cores.

Radiometric dating of ice has not been widely applied so far. A number of isotopic systems have been investigated for this purpose, but the low levels of the radioactive species in question have hampered progress. Improvements in analytical techniques may change this situation in the future (Aciego et al., 2011) and a robust radiometric dating technique for ice is highly desirable.

Another common strategy is to use the fairly well understood physics of ice flow and thinning to estimate the depth–age relationship for an ice core. Such estimates can be checked or constrained by assuming the ages of key climate transitions (e.g., glacial–interglacial transitions) recorded in ice-core isotope (or other) records, or can be correlated to chronologies of ocean sediment records. The deepest Antarctic records have been dated in this way (e.g., EPICA Community Members, 2004).

Gas records in ice cores also provide dating techniques. One approach is to use globally synchronous variations in trapped atmospheric gases as tools to create precise relative chronologies between ice-core records (Bender et al., 1994; Blunier and Brook, 2001). This allows two ice cores (e.g., one in Greenland and another in Antarctica) to be placed on common chronologies, allowing precise comparisons between them. The isotopic composition of atmospheric oxygen in the ice-core record can also be correlated with the marine isotope record and its established chronology (Sowers et al., 1993). More recently, Bender (2002) showed that the O_2/N_2 ratio of trapped air in the Vostok ice core varies in a way that appears to be coherent with insolation variations on timescales associated with orbital precession, and tuning O_2/N_2 records to local insolation can provide chronological control (Kawamura et al., 2007).

Correlation of various parameters in ice cores to a variety of other independently dated records can also assist in creating ice-core chronologies. Variations in cosmogenic isotopes (e.g., ^{10}Be) in the ice core can be correlated to well-dated oscillations in the tree-ring ^{14}C record (Taylor et al., 2004). Stable isotope records from cave deposits are dated accurately using U-series dating and show variations that are apparently synchronous with fluctuations in Greenland ice-core records (Wang et al., 2001). Peaks in volcanic sulfate in ice cores can be correlated to dates of historically known volcanic eruptions, providing an extremely important check on layer-counting chronologies (Meese et al., 1994).

Proxy and Other Measurements in Ice Cores

A variety of chemical and physical measurements are performed on ice core samples, intended to infer something about past environmental conditions. Some of the more notable environmental 'proxies' are reviewed briefly below. Space limitations prevent mention of all the areas of study, and the reader is referred to other sections of this encyclopedia for more detailed information.

Visual Stratigraphy and Other Physical Measurements

The thickness of annual layers provides a first-order record of snowfall variations (Figure 2), after corrections for thinning due to glacier flow, which can be made fairly accurately in many situations (Cuffey and Clow, 1997). Past precipitation rates are an extremely important paleoenvironmental parameter and are often correlated with temperature in the polar regions. Layer counting is laborious but extremely informative. New techniques combine visual stratigraphy with seasonal variations in other parameters to provide multiparameter dating and accumulation rate estimates, and algorithms have been developed to automatically count annual layers in some of these variables (Taylor et al., 2004).

The distribution of summer melt layers in ice cores is another visual measurement that provides climate information (more melt layers associated with warmer summer temperatures; Alley and Anandakrishnan, 1995). Melt layers are formed when surface snow melts and the meltwater percolates in to the snow-pack and collects in a layer at shallow depth, probably along high-density snow surfaces. Melt layers are visible as bubble-free ice layers, and their distribution can be counted as a function of time.

Other physical properties of the ice accessible by visual observation or basic physical measurements include the orientation and size of ice crystals, size and distribution of bubbles, disappearance of bubbles as clathrate forms at depth, and ice density. Careful measurements of these properties provide the context for interpreting climate records as well as understanding stratigraphic discontinuities, anomalous ice flow, and ice sheet dynamics in general (i.e., Gow et al., 1997).

Stable Isotopes

The stable isotopic composition of ice ($\delta^{18}O$ and δD) has long been used as a paleotemperature indicator, with original work on this subject begun in the 1960s and 1970s. The temperature

dependence of the isotope ratios arises as a result of fractionation during transport from a moisture source to the ice-core site. The processes involved are complex, but the basic concept is that lower temperatures allow a greater isotopic ‘distillation’ as moisture travels to the ice-core site. Measurements of isotope ratios in high-latitude precipitation show the expected trend of lighter ratios with lower temperature. The modern relationship can be used to calculate past temperature change from ice-core isotope records, but numerous recent studies employing bore-hole temperatures and nitrogen and argon isotopes show that the modern ‘spatial’ slope is probably not always appropriate for past conditions. These studies suggest that, in Greenland, past isotope variations have a greater sensitivity to temperature change than indicated by the spatial slope (Severinghaus and Brook, 1999), but in Antarctica, the spatial and temporal sensitivities appear to be similar.

The ratios $\delta^{18}\text{O}$ and δD have been measured somewhat interchangeably in the history of ice-core research. There are small differences between the responses of these two ratios to environmental conditions though, expressed as a parameter called ‘deuterium excess.’ Its primary use is as a monitor of the conditions (primarily temperature) at the moisture source. This is important for understanding the impact of moisture source changes on the isotope–temperature calibration, as well as low-latitude climate change.

In contrast to the polar regions, the systematics of isotope records in mid and tropical latitudes is more complex and inferences of temperature change more difficult.

Greenhouse and Biogenic Gases

The most unique aspect of ice-core records is the archive of ancient atmosphere that they provide. Air is trapped at the base of the firn layer where compacting snow finally turns to ice and the trapped air is present in small bubbles (Figure 3).

The depth of this transition varies with temperature and accumulation rate but is ~50–100 m below the surface at polar sites. For this reason, there is an offset between the age of the air and the age of the ice, which is accounted for with glaciological models of firn densification and gas trapping. Air in

Figure 3 Air bubbles in a thin section of ice from ~140 m depth at the GISP2 ice coring site in Greenland.

bubbles is extracted by melting, crushing, or grating ice in vacuum. Dry techniques of crushing or grating are required for some gases, such as carbon dioxide.

Detailed records of the three main biogenic greenhouse gases, namely, carbon dioxide, methane, and nitrous oxide, are available from ice cores from Greenland and Antarctica. These records cover time periods as recent as the rise of the levels of these gases over the last few centuries to long-term glacial–interglacial cycles going back over 800 000 years. The overall reliability of the gas records can be demonstrated by the overlap of ice-core records with instrumental measurements that started in the 1950s and agreement between ice cores from different locations. Analytical or preservation artifacts impact these data in some cases, but are fairly well recognized. Early carbon dioxide records from Greenland are compromised by melt layers, which have elevated carbon dioxide levels because of the high solubility of carbon dioxide in water. As a result, only carbon dioxide records from colder locations in Antarctica are deemed reliable. Methane records do not suffer from this problem, but, very occasionally, high levels are found in basal ice from ice cores, possibly related to the presence of microbes associated with particle-rich layers (Tung et al., 2005). Nitrous oxide has proved somewhat more problematic. Elevated levels of nitrous oxide are associated with elevated dust levels in several ice cores (Schilt et al., 2010; Sowers, 2001; Spahni et al., 2005) and the controls on these elevated levels are not completely understood. Nonetheless, reliable data can apparently be obtained by selecting samples with low particulate concentrations (Spahni et al., 2005).

More recent work expands this field by using the stable isotopic composition of the three major biogenic gases to constrain sources and sinks (Elsig et al., 2009; Ferretti et al., 2005; Indermühle et al., 1999; Laurantou et al., 2010; Smith et al., 1999; Sowers et al., 2003) and by investigating the possibility of reconstructing levels of rarer gases that are important components of global biogeochemical cycles, for example, carbonyl sulfide, methyl bromide, and methyl chloride (e.g., Aydin et al., 2004; Montzka et al., 2004; Saltzman et al., 2004).

Finally, trace gas records from firn air deserve mention. The firn is the unconsolidated snow pack. Gas diffusion in the firn is sufficiently slow so that firn contains air with a mixture of gases that increase in age with depth. The significance of this is that large volumes of air can be pumped from the firn for measurements, which would otherwise be impossible with traditional ice samples (e.g., Fain et al., 2009; Montzka et al., 2004; Trudinger et al., 2002).

N, O, Ar, and Other Noble Gases

Although greenhouse gas records from ice cores receive attention with respect to the modern global warming problem, equally interesting paleoenvironmental information is available from the major gases in air trapped in ice (O_2 , N_2 , and Ar), other noble gases, and the isotopes of these gases.

Atmospheric O_2 is important in ice-core records because its stable isotopic composition ($\delta^{18}\text{O}$) is slaved to that of the ocean through global photosynthesis and respiration. Ocean $\delta^{18}\text{O}$ varies as the ice sheets grow and shrink through glacial–

interglacial cycles. The turnover time of O_2 in the ocean-atmosphere system is long with respect to the atmospheric mixing time, so $\delta^{18}O$ of O_2 variations are synchronous everywhere on the Earth, providing stratigraphic markers for ice-core chronologies (Bender et al., 1994).

The isotopic composition of nitrogen ($\delta^{15}N$ of N_2) is influenced by gravitational fractionation in the firm, and can be used to correct other isotopes for this fractionation (atmospheric $\delta^{15}N$ of N_2 is thought to be constant on million-year timescales). More importantly, nitrogen and argon isotope ratios have also been used together as paleothermometers, taking advantage of a phenomenon known as ‘thermal diffusion,’ which causes fractionation in a temperature gradient. Nitrogen and argon data can be used together to deconvolve gravitational and thermal signals and calculate the magnitude of temperature change associated with fast changes in climate recorded in ice-core records (Grachev and Severinghaus 2003a; Grachev and Severinghaus 2003b; Severinghaus and Brook, 1999; Severinghaus et al., 1998), thus providing an important independent paleothermometer.

These gases also have other uses. Ratios of O_2 , N_2 , Ar, Xe, and Kr provide important information on gas loss during bubble close-off or storage (Severinghaus and Battle, 2006) (because of the size dependence of loss processes) and on the possible influence of melting on the gas content of ice samples (because of the differences in solubility). Studies of these gases in firm air provide insight into processes that transport air in the firm and their significance in the interpretation of the ice-core record (Kawamura et al., 2006).

Borehole Temperatures

The vertical temperature profile of an ice sheet can contain information about the past surface temperature history. Borehole temperature profiles are measured by suspending temperature sensors in fluid-filled boreholes and recording the temperature as a function of depth using highly accurate and precise instrumentation. This is an important area of study because it can provide independent estimates of temperature change that complement the stable isotopes of oxygen and hydrogen in ice and the nitrogen and argon isotopic work described above. The basic idea is that the ice sheet remembers past surface temperature changes because these propagate through the ice as a result of heat transport. If heat transport properties of the ice, as well as the geothermal heat flux, are known, the temperature profile can be inverted to provide a record of surface temperature change, which is independent of proxy calibration. Analogous work is done with continental boreholes to measure warming trends over the past few centuries. Such records are smoothed representations of more abrupt changes due to the nature of heat transport, but provide extremely important information, for example, the first estimate of very large glacial–interglacial temperature change in Greenland, revealing complications with the stable isotope thermometer (Cuffey et al., 1995).

Glaciochemistry

The chemical composition of ice-core samples provides information about past changes in atmospheric circulation, dust loading, volcanic eruptions, biological activity, human impact

on the environment, and a wealth of other information. In general, this area of research includes measurements of soluble species (those released to solution when ice samples are melted), as opposed to studies of insoluble particles (below). The distinction between soluble species and very small particles is operational but not significant for the purposes of this discussion.

Chemical measurements at a variety of sites reveal the human impact on the atmosphere. For example, records of lead concentration in Greenland ice (Figure 4) reveal the large impact of industrial lead, and show how it has changed with regulation of leaded gasoline and other global political–environmental changes (McConnell et al., 2002a,b). Many other pollutant species are present in the ice as well.

On longer timescales, soluble chemistry records the impacts of major volcanic eruptions through peaks in volcanic sulfate deposition. These data provide information about the frequency of eruptions and the climate impact of large volcanic eruptions, and, when the age of the eruption event is known (i.e., Zielinski et al., 1994), they provide independent tests of ice-core chronology.

The major ion chemistry of ice cores is useful in a more general way as a tracer of the input of chemical species from continental dust, sea salt, and biogenic processes. For example, calcium concentrations are believed to largely reflect the dustiness of the atmosphere, and sodium and chloride are largely derived from the ocean and their concentrations may reflect the proximity to open water (which may change as climate changes), other aspects of meteorology that influence the transport of marine air to ice-core sites, or more complex processes related to the behavior of salts on sea ice surfaces (Rankine and Wolff, 2002). Major ions commonly measured in ice include Na^+ , Mg^{2+} , Ca^{2+} , K^+ , NH_4^+ , Cl^- , NO_3^- , and SO_4^{2-} , and organic acids such as methylsulphonate and CH_3SO^- , and multivariate statistical analysis has been used to attempt to describe the relationship between the deposition of these species and meteorological parameters. Many of these species are measured by ion chromatography using continuous melter systems that provide a continuous sample stream, creating very high resolution datasets.

More recently, the advent of high-sensitivity Inductively coupled plasma (ICP) mass spectrometers has opened a new window in glaciochemistry, allowing for measurements of many trace species in ice at very high resolution (McConnell et al., 2002a,b).

Insoluble Particles

The insoluble particulate content of ice cores includes mineral dust, volcanic ash, and extraterrestrial material (discussed below), and potentially contains important information about the dustiness of the atmosphere in past times, and, through the particle size distribution, possibly information about past wind speed. Particle abundances in most ice cores are very low, and optical or electrical sensing methods on solid or liquid samples have been used to produce continuous or semicontinuous records of particle numbers and sizes. Bulk dust data generally show the strong glacial–interglacial cycles, with higher levels of dust in cold glacial periods. For example, a recent long dust record from the East Antarctic EPICA Dome C core clearly shows glacial–interglacial dust cycles (Figure 5; Jouzel et al., 2007). The amplitude of the cycles is too large to

Figure 4 A 330-year continuous ice-core record of Pb concentration, flux, and relative enrichment at the D5 ice core site (68.5°N , 42.9°W) in west central Greenland. Reproduced from McConnell JR, Lamorey GW, and Hutterli MA (2002a) A 250-year high-resolution record of Pb flux and crustal enrichment in central Greenland. *Geophysical Research Letters* 29: 2130; McConnell JR, Lamorey GW, Lambert SW, and Taylor KC (2002b) Continuous ice-core chemical analyses using inductively coupled plasma mass spectrometry. *Environmental Science and Technology* 36: 7–11.

Figure 5 The dust and δD records from the EPICA Dome C ice core in Antarctica (EPICA Community Members, 2004; Jouzel et al., 2007; Lambert et al., 2008).

be explained by changes in ice accumulation rate alone, implicating a dustier, drier atmosphere, or changes in atmospheric circulation patterns that bring dust to this high-latitude site.

The chemical and isotopic composition of insoluble dust can provide important information about the source of dust to remote ice-coring sites. This work is difficult because of the low levels of dust involved and the sample size requirements for some of the techniques. Isotopic fingerprinting using lead, strontium, and neodymium isotope ratios suggests, for example, that most of the dust at central Greenland sites is derived from low-latitude regions of east Asia (Biscaye et al., 1997), and that the dust in east Antarctica originates mainly from the Patagonian region of South America, with possible contributions from other areas (Delmonte et al., 2004).

Particles of volcanic origin (glass shards or tephra) can sometimes be identified uniquely in ice-core samples, providing a history of volcanic activity and, in some cases, datable time horizons useful for ice-core chronology.

Cosmogenic Isotopes and Extraterrestrial Material

Ice cores contain several kinds of information about extraterrestrial phenomena. Cosmogenic isotopes (produced by cosmic rays) produced in the atmosphere are deposited on the ice sheet, providing a record of the processes that produce and modulate the cosmic ray flux, and influence their deposition rates, including changes in solar activity and the Earth's magnetic field (e.g., Muscheler et al., 2005). ^{10}Be (half-life 1.5×10^6 years) and ^{36}Cl (3.0×10^5 years) are the most commonly measured cosmogenic isotopes in ice. ^{10}Be data record the influence of a geomagnetic excursion (the Laschamp excursion) around 41 000 years ago, and detailed records show variations related to the modulating effects of the solar wind on cosmic ray flux at high latitudes (Finkel and Nishiizumi, 1997). In addition to revealing the modulating effects, these features provide chronological ties that can be used to correlate ice cores and constrain ice chronologies. These data have relevance beyond ice-core studies because of the significant influence of these modulation processes on the production of radiocarbon in the atmosphere and the resulting implications for the radiocarbon timescale. ^{10}Be data have also been used as accumulation rate constraints, assuming a constant ^{10}Be flux and fraction of dry versus wet deposition (e.g., Raisbeck et al., 1987; Steig et al., 1998), although in detail this assumption may not be correct.

Ice cores also contain meteoritic material, albeit in small quantities given the limited sample availability (micrometeorites have been extracted from large surface samples of melted snow and ice for some time, but given the limited size of ice samples, this type of work is not practical for deep ice cores). Isotopic and elemental measurements of species enriched in meteoritic material, including iridium (Gabrielli et al., 2004; Karner et al., 2003) and ^3He (Brook et al., 2000, 2009), can be used to examine possible changes in flux of extraterrestrial dust to the earth, although this field is in its infancy.

Biological Material in Ice

Although the existence of life in harsh environments has been a topic of research for quite some time, studies of life in ice have flourished in the last decade or so. This work is difficult due to potential contamination issues and low levels of biological

material preserved in ice. Current attention focuses on the possible viability of microorganisms in ice; characterization and preservation of ancient DNA and RNA; preservation of fungi, spores, and other organisms; and implications for life in subglacial lakes and in ice on other planets.

Major Highlights of Ice Core Research

This section is a brief review of some of the major patterns and findings of ice-core research. Space limits this review to a few key issues – the remainder of the ice-core section of this encyclopedia provides much more relevant details.

Glacial–Interglacial Cycles

Deep ice cores from Antarctica are the only ice-core records to penetrate beyond the end of the last interglacial period. In Greenland, there are tantalizing hints (Landais et al., 2003; Suwa et al., 2006) of this penultimate interglacial near the base of the ice sheet, but no complete sections have yet been obtained. Until recently, the oldest Antarctic record was that of the east Antarctic core from Vostok station, extending back through four glacial–interglacial cycles to ~440 000 years before present (Petit et al., 1999).

An ice core on Dome C drilled by the European Program for Ice Coring in Antarctica (EPICA) collaboration recovered a core with at least 800 000 years of interpretable record, almost doubling the Vostok achievement (EPICA Community Members, 2004; Jouzel et al., 2007). Records from EPICA Dome C (Figure 6) clearly show the strong 100 000 year cyclicity in climate well known from marine sediments. One of the major achievements of this drilling program is the complementary carbon dioxide, methane, and nitrous oxide records (Loulergue et al., 2008; Lüthi et al., 2008; Siegenthaler et al., 2005; Spahni et al., 2005), which clearly show how closely the concentrations of these gases follow Antarctic climate patterns and how unusually the modern values of these gases are viewed in the context of over 800 000 years of Earth's history.

The relationship between the gas records, particularly carbon dioxide, and Antarctic and global temperatures is a subject of intense research, and has been so since the original publication of long Antarctic carbon dioxide records in the 1980s. A major question concerns the timing of carbon dioxide and temperature change on these timescales. Most studies of this issue have concluded that there is a lag of several hundred to several thousand years between temperature change and carbon dioxide change (temperature leads carbon dioxide), suggesting that warming, triggered by other factors, causes a change in the carbon cycle that increases carbon dioxide, which is then a positive feedback on warming. Another major question concerns the ultimate cause of the carbon dioxide variations. It is widely believed that they are caused by changes in the ocean carbon cycle, either as a result of changes in partitioning of carbon between the deep and surface ocean due to changes in ocean circulation, or because of changes in biological productivity that transfer carbon from the surface to the deep ocean (Sigman and Boyle, 2000). Despite several decades of work, the ultimate cause of the carbon dioxide cycles remains elusive.

Figure 6 Composite records of atmospheric carbon dioxide and methane from the EPICA Dome C, Vostok, and Taylor Dome ice cores in Antarctica (Louergue et al., 2008; Lüthi et al., 2008; Siegenthaler et al., 2005; Spahni et al., 2005) and the δD record (EPICA Community Members, 2004; Jouzel et al., 2007).

Abrupt Change, the Last Ice Age, and the Holocene

In contrast to the long march of long-term climate cycles seen in the longest Antarctic ice cores, cores from central Greenland have revealed a remarkable pattern of more rapid climate change during the last Ice Age (Figure 7). This more abrupt style of climate change is often referred to as ‘millennial-scale climate change,’ although the abrupt warmings and coolings in the Greenland records are just specific examples of change on this timescale.

Although the first deep ice cores drilled in Greenland showed these abrupt climate shifts, it was not until the recovery of the parallel Greenland Ice Core Project (GRIP) and Greenland Ice Sheet Project 2 (GISP2) ice cores from central Greenland in the early 1990s that the significance of these abrupt shifts was recognized more widely outside.

The stable isotope records from central Greenland deep cores (Figure 7) show a sequence of more than 20 abrupt warming and cooling events during the last Ice Age (from ~120 000 to 10 000 years ago). These events, called ‘Dansgaard-Oeschger events’ after their discoverers Hans Oeschger and Willi Dansgaard, are remarkable for their frequency, size, and abruptness. Detailed studies of the isotopic variations and associated changes in layer thickness indicate that the cold-warm transitions are very abrupt (changes in mean accumulation rate take place over decades or less; Alley et al., 1993), and represent large temperature changes (~10–15°). These observations have led to a large amount of research dedicated to understanding the causes of abrupt climate change, their manifestation in other parts of the world, and the possibility of their recurrence in the future.

An intriguing aspect of millennial-scale climate change is that Antarctic ice cores do not record a pattern similar to that of Greenland. Instead, Antarctic isotope records seem to show a

‘see-saw’ relationship, where large warming events in the Northern Hemisphere are preceded in the South by more gradual warming that terminates at the time of abrupt warming in the North. The pattern has been attributed to changes in ocean heat transport associated with the D–O events (Knutti et al., 2004 and references therein), although other explanations have been suggested (Wunsch, 2003).

Following the last abrupt climate shift recorded in Greenland (the end of the Younger Dryas period), climate variation was significantly muted compared to the last Ice Age, with one notable abrupt cool event at about 8.2 ka (Alley et al., 1997). Other aspects of the Greenland records are not as uniform in the Holocene. For example, Mayewski et al. (2004) discuss oscillations in major ion concentrations that they relate to polar cooling and tropical drying. Atmospheric methane levels dropped dramatically during the early Holocene, and then rose after ~5000 years ago. Atmospheric CO₂ rose from an early Holocene low at ~8000 years ago to the late Holocene value of ~280 ppm by 1000 years ago. Antarctic stable isotope records also do not indicate large, abrupt changes during the Holocene, but temporal trends related to changes in ice sheet elevation, an early Holocene climate optimum 11 500–9000 years ago, and shorter-term millennial events are apparent (Masson et al., 2000).

Recent and Anthropogenic Change

As mentioned above, ice cores record in great detail the anthropogenic impact on the remote atmosphere. Records of pollutants such as lead and sulfate are preserved in annual resolution, and the rise of greenhouse gases in the ice core records provides fundamental information relevant to the modern global warming problem (Figure 8).

Figure 7 Records of millennial-scale variations in stable isotope records from Greenland (GISP2 ice core) and Antarctica (Byrd ice core). Reproduced from [Blunier T and Brook EJ \(2001\)](#) Timing of millennial-scale climate change in Antarctica and Greenland during the last glacial period. *Science* 291: 109–112.

Figure 8 Records of the greenhouse gases carbon dioxide, methane, and nitrous oxide, showing the anthropogenic increase over the last two centuries. Data from ice cores ([MacFarling Meure et al., 2006](#)) and direct atmospheric measurements, compiled and updated on the basis of publicly available data provided by the National Oceanic and Atmospheric Administration Earth Systems Research Laboratory.

New data on a variety of trace gas species and their isotopes in firn air and ice promise to improve our understanding of anthropogenic change, as do high-resolution studies of trace elements. Equally important are new networks of annually resolved records that will allow for greater understanding of the spatial distribution of climate change at high latitude and altitudes, through programs such as ITASE and PARCA. These regional assessments are critical for adequately assessing the influence of greenhouse warming at high latitudes.

Future of Ice Coring

Data from ice cores underpin much of global change science, and in the last two decades have provided more detailed and longer views of atmospheric and environmental change in the polar regions than perhaps originally envisioned. The oldest records are 800 000 years old, and records from areas of high snow accumulation provide annual data for tens of millennia. Cores from high elevation sites in the tropics and mid-latitudes, obtained by heroic measures, provide important information about climate change in these regions, unavailable from other means.

The future of ice coring involves both collecting more cores, to examine spatial variations in environmental change, and collecting older cores, to extend the record as far back as possible. A broad-based international program called International Partners in Ice Coring Sciences is involved in planning major new coring programs. For example, cores penetrating the last glacial transition and Greenland and Antarctica show significant inter-hemispheric differences, as well as differences in the character of deglacial climate change within Antarctica. Fully understanding the nature of this large change in the earth system requires a detailed and well-dated spatial map of the progression of the deglaciation; a network of deep ice cores in Greenland and Antarctica could accomplish this. On shorter timescales, a key global change question concerns separating anthropogenically forced climate change from natural variability. For this question, a network of cores in both polar regions and other parts of the world covering the last 2000 years is desirable. For older cores, a major goal in Antarctica is an ice-core record back to 1.2 or even 1.5 My. Such a core would extend through the mid-Pleistocene transition, a time period where Earth's climate shifted from 40 000 to 100 000-year climate cycles. This core would allow investigation of the role of greenhouse gases in this transition, as well as provide a detailed land-based record of the evolution of temperature and other environmental variables over this time period. In Greenland, a core in a location that will allow recovery of the Eemian, or last interglacial, period, is a major goal.

Introduction

Snow falling on polar and high-altitude regions has formed $\sim 1.6 \times 10^7$ km² of glacial ice that provides an invaluable archive of past conditions on Earth. The expansive ice sheets of Greenland and Antarctica cover $\sim 10\%$ ($> 1.5 \times 10^7$ km²) of the Earth's terrestrial surface with ice and contain $\sim 70\%$ of the freshwater on the planet (Paterson, 1994). Temperate glaciers cover more than 5×10^5 km² and comprise $\sim 3.5\%$ of the glacial ice on our planet (Table 1). The present volume of the Earth's glacier ice, if totally melted, represents about 80 m in potential sea-level rise with 91%, 8%, and 1% represented by the East and West Antarctic Ice Sheets, the Greenland Ice Sheet, and mountain glaciers, respectively (Hambrey and Alean, 2004).

Research on ice cores from polar and temperate glaciers has focused primarily on the reconstruction of the paleoclimate record to determine the mechanisms responsible for ice-sheet mass balance, associated sea-level change, and the processes leading to the transition between glacial and interglacial periods (e.g., Petit et al. (1999) and Alley (2002)). Ice cores collected from Greenland before the 1990s provided important evidence showing persistent climate instability over the last glacial cycle. Data from the Antarctic Vostok ice core have shown that over the past 400 ka, there was a clear correlation between temperature and greenhouse gases, implying that greenhouse gases contributed to the temperature observations during this period. A recent ice core collected at Dome C as part of the European Project for Ice Coring in Antarctica (EPICA) has extended this record to 650 ka and may ultimately produce a gas record 900 ka old (EPICA, 2004; Brook, 2005; Siegenthaler et al., 2005; Spahni et al., 2005). Information derived from the ice-core record allows predictions of future changes in climate and provides important data to anticipate how these changes will impact future societal issues on our planet.

Atmospheric impurities deposited in glacial ice include aerosols emitted by the oceans and the continents, and anthropogenic activity. Figure 1 shows the process of glacial deposition together with the global distribution of glaciers on our planet. The cold, dry conditions typical of glacial periods reduced the hydrological cycle and precipitation rate. The reduced precipitation increased the residence time of aerosols and dust allowing them to disperse to great distances. This paradigm is revealed in the dust record from the Vostok ice core, which shows that dust concentrations during glacial periods were ~ 50 times greater than for interglacial periods (Petit et al., 1999; Figure 2). The isotopic (Sr and Nd) composition of dust in the Vostok core further shows that it originated in the Patagonian region of South America (Delmonte et al., 2004). Unfortunately, the biogenic nature of the eolian dust particles in glacial ice has received relatively little attention despite its known role in microbial transport (Griffin et al., 2003).

The biological contents of ice cores were first investigated in the 1980s by Abyzov (Abyzov, 1993; Abyzov et al., 2001), who used microscopic observations and traditional cultivation methods to show that microorganisms were present in the Vostok ice core and were positively correlated with the concentration of dust particles. An example of dust and associated microbiota in the Sajama ice core, Bolivia, is shown in Figure 3. Abyzov's results, although controversial, motivated other microbiologists to examine the biotic content of ice cores collected from many icy regions of our planet (e.g., Priscu et al. (1998, 1999), Karl et al. (1999), Christner et al. (2000, 2001, 2003), and Castello et al. (2005)). Anomalies in the concentration and isotope ratio in biogenic trace gases (e.g., CH₄, N₂O) trapped in temperate and polar glacial ice have led glaciogeochemists to suggest enzymatic alteration within the ice by *in situ* metabolism (Sowers, 2001; Campen et al., 2003; Tung et al., 2005). These trace gas anomalies imply that microorganisms are actually metabolizing in solid ice following deposition. Collectively, these data infer that ice cores represent 'ice museums' containing novel records of evolution and habitat variability on our planet. Clearly, biologists should be included in future ice-coring efforts if we are to produce a comprehensive record of past conditions on Earth. We present an overview of recent investigations that focus on biogenic matter in ice cores collected from polar ice sheets (Antarctica and Greenland) and from low-latitude mountain glaciers. We conclude by discussing the metabolic and evolutionary potential of ice-bound microorganisms.

Table 1 Aerial coverage of selected glaciated areas on Earth

Region	Surface area (km ²)	Percent of world total
<i>Polar</i>		
Antarctica	13,593,310	87.5
Greenland	1,726,400	10.88
<i>Polar total</i>	15,319,710	96.58
<i>Temperate</i>		
Africa	10	<0.01
Asia and Eastern Europe	185,211	1.17
Australasia (i.e., New Zealand)	860	0.01
Europe (Western)	53,967	0.34
North America excluding Greenland	276,100	1.74
South America	25,908	0.16
<i>Temperate total</i>	542,056	3.42
<i>World total</i>	15,861,766	

Data from the World Glacier Monitoring Service, 1989.

Biogenic Matter in Polar Ice Sheets and Temperate Mountain Glaciers

The study of biogenic material in ice cores is in its infancy and, except for a few reports, was unheard of a decade ago. We now know that microorganisms and associated nonliving organic matter are present in virtually all ice samples examined for biological properties (Figure 4). The past decade has seen biological research in ice cores go from a novelty to a focused area of scientific research.

The Vostok Ice Core

Vostok Station is centrally located on the East Antarctic Ice Sheet (78°27'51" S 106°51'57" E; altitude 3,448 m a.s.l.) and sits over ~3,743 m of ice. Nearly 20 yr after Vostok Station was constructed for the purpose of paleoclimatic ice-core research, airborne radio-echo surveys and satellite images revealed that a

very large lake (Subglacial Lake Vostok) exists beneath the ice sheet (Kapitsa et al., 1996; Studinger et al., 2004) (Figure 5). A 3,623-m core (designated 5 G) was recovered from the ice sheet by an international drilling team in 1998 before drilling was terminated ~120 m from the ice-water interface to prevent contamination of the lake environment.

The upper 3310 m of the Vostok ice core has provided a detailed paleoclimate record spanning the past 420 ka (Petit et al., 1999). However, the deepest portion of the ice core (3539–3623 m) has a chemistry, isotopic composition, and crystallography distinctly different from the overlying glacial ice (Jouzel et al., 1999; Figure 6). Geochemical and physical data from this deep ice indicate that it originated from the freezing (accretion) of subglacial lake water to the underside of the ice sheet. Microbiological studies of the Vostok glacial and accreted ice have indicated that low, but detectable, concentrations of prokaryotic cells (34–430 cells ml⁻¹; Christner et al., 2006) and DNA are present (Priscu et al., 1999; Christner et al., 2001; Bulat et al., 2004), and a portion

Figure 1 History of entrapped particles in glacial ice and the present-day distribution of glaciers. (a) Schematic illustrating the range of source environments that contribute particles to the atmosphere. (b) Advective currents, created by solar generated infrared radiation, inject surface derived aerosols high in the atmosphere. Such aerosols (red dots) may serve as primary ice nuclei in clouds, and are subsequently precipitated in snowfall or rain. (c) In geographical locations where the annual temperature remains cold enough for snowfall to accumulate annually, particles from the atmosphere are archived in a chronological sequence in firn and glacial ice. (d) Global locations of present-day ice sheets and mountain glaciers (in blue). Each glacial environment is unique, as the nearest ecosystems that would most likely contribute the majority of airborne biological particles are very different. Distribution data based in part on Satellite Image Atlas of Glaciers of the World (US Geological Survey, (2002) Satellite Image Atlas of Glaciers of the World).

Figure 2 The climatic record over the last 420 ka deduced from the first 3310 m of the Vostok ice core (adapted from Petit et al. (1999)). From top to bottom: Global ice volume (black, in relative units, redrawn from the data of Petit et al. (1999)) as deduced from the marine sediment record; temperature (orange, difference with the present surface temperature) deduced from the stable isotope composition of the ice; records of CO₂ (green, ppmv) are deduced from entrapped air bubbles; profile of continental dust concentration (blue, ppm).

Figure 3 Dust layer, core particles, and associated microorganisms. (a) Cross-sectional view of ice core recovered 112 m (deposited, ~12 ka BP) below the surface from the Sajama ice cap, Bolivia. A large number of entrapped gas bubbles and macroscopic particles are visible. A prevalent dust layer is shown (pink arrows), characteristic of the increased concentrations of airborne particles associated with dry climatic conditions. (b) Low-resolution scanning electron micrograph illustrating the range of biological and inorganic particles entrapped in this ice-core sample. (c) Pennate diatom that most likely originated from one of the many saline lakes and salt flats in the area. (d) Rod-shaped bacteria preserved within the ice.

of the entrapped microbial assemblage is metabolically active when melted and exposed to nutrients (Karl et al., 1999; Christner et al., 2001). Many of the bacterial cells are associated with nonliving organic and inorganic particulate matter (Figure 7). Molecular identification of microbes within the accreted ice (by both culturing and direct 16S rDNA

amplification) show close agreement with present-day surface microbiota that classify within the phyla Proteobacteria (α , β , and γ), low G+C Gram-positives, Actinobacteria, and the Cytophaga-Flavobacterium-Bacteroides line of descent (Priscu et al., 1999; Christner et al., 2001; Bulat et al., 2004). Recent data from the Vostok ice core, using electron backscatter

Figure 4 Scanning electron micrographs of particles from polar and nonpolar regions on Earth. Images in the left panel of each set are low-resolution micrographs ($1000\times$) illustrating the elevated concentrations of particles from nonpolar regions. The right panels show selected images of prokaryotic cells (Taylor Dome and Lake Vostok), an organic fiber (NGRIP), a diatom (Sajama), and a pollen grain (Guliya).

scanning electron microscopy, have also shown that up to 40% of the particles in glacial ice from the Vostok core represents nonliving biogenic matter; this value reaches 60% for accretion ice (Figure 8; Royston-Bishop; unpublished data). Dissolved organic carbon (DOC) in the Vostok core ranges from 0.2×10^{-5} M to 2.7×10^{-5} M in glacial ice and increases to 10.1×10^{-5} M in the underlying accretion ice. The dissolved and particulate organic fractions are positively correlated, inferring that these constituents covaried in the atmosphere when deposited on the ice sheet or were produced within the glacial ice by complimentary *in situ* metabolic activity following deposition. The positive relationship between these fractions in accretion ice could result from complimentary *in situ* metabolism in either the ice itself or within Lake Vostok before the ice accreted to the bottom of the ice sheet.

There has been speculation that geothermal input into Lake Vostok may fuel chemolithoautotrophic (organisms that use CO_2 as their carbon source and reduction/oxidation reactions for energy) microbial communities (Bulat et al., 2004). More importantly, it is still possible for a chemolithoautotrophic-based ecosystem to exist without invoking geothermal activity. A range of energy-rich reduced compounds (e.g., HS^- , S^0 , and Fe^{2+}) are supplied to the lake by the ice sheet itself, which alone can supply the energy and carbon required to support metabolic activity within the lake. Organisms trapped in the ice sheet can also provide the microbial seed to initiate the lake population (Priscu et al., 1999; Karl et al., 1999). Although geothermal input is not required to support life within the lake, it can provide an additional energy source for microbial growth in the lake if present. While other views of life in Lake Vostok exist, they all imply that microorganisms are present in this subglacial environment, despite high pressure, constant cold, low nutrient input, and an absence of sunlight (e.g., Bulat et al. (2004), Petit et al. (2005), Priscu et al. (1999), and Karl et al. (1999)). The exact nature of the biology in Lake Vostok awaits direct sampling of the lake water.

Figure 5 (a) Satellite image of Antarctica showing the location of Lake Vostok (yellow box). Digital mosaic compiled by the Canadian Space Agency (Alaska SAR Facility) using data from RADARSAT-1. (b) Image shows a perspective view of the ice surface above Lake Vostok compiled from ERS-1 radar altimeter data. Lake Vostok is the flat, featureless area formed where the glacial ice overrides the actual lake. Image courtesy of M. Studinger (Lamont Doherty Environmental Observatory, Columbia University, New York) using RAMP elevation data provided by the National Snow and Ice Data Center (NSIDC).

Ice Cores from Greenland

Biological studies of glacial ice cores have focused primarily on Antarctic cores and nonpolar, high-elevation glaciers (Priscu and Christner (2004) and references within). However, new studies on ice cores drilled in Greenland (i.e., GISP2, Gow et al. (1997), and NGRIP, Anderson et al. (2004)) have yielded important data on the nature of biogenic matter within and below the Greenland Ice Sheet. Culturable bacteria were recovered from the 'silty' ice in the basal portion of the GISP2 core,

Figure 6 Schematic of the Vostok ice core showing the region of transition between glacial and accretion ice. The accretion ice is represented by (dirty) ice containing numerous sediment inclusions and clear ice, which was formed over the lake proper and is relatively free of sediment. The ice below 3623 m has recently been collected but has yet to be analysed; it is thought to have formed over the lake proper. See Jouzel et al. (1999) for details of the transition zone.

Figure 7 (a,b,c) Scanning electron and (d) atomic force microscope images of bacterial cells from Vostok accretion ice showing their close association with organic particles. The large particle in (a) was shown to be organic using backscattered electron imaging. The numbers on each panel refers to the depth from which the ice cores were collected. Samples for microscopy were prepared as outlined by Priscu et al. (1999). Arrows in 'a' denote the location of bacterial cells.

with reported total cell concentrations $>10^7$ cells ml^{-1} of meltwater (Sheridan et al., 2003; Miteva et al., 2004). The bacteria entrapped in the deepest sediment-laden portion of the GISP2 core could have originated from both the overlying 120 ka-old glacial ice and the underlying glacial till. Phylogenetic analysis of 16S rRNA gene sequences in the silty ice revealed that 36% of the bacterial isolates obtained were related to genera previously documented in glacial and permanently cold environments (i.e., *Methylobacterium*, *Rhodococcus*, *Mycobacterium*, *Sphingomonas*, *Arthrobacter*, and *Frigoribacterium*; Miteva et al. (2004)), providing support for the notion that members of these genera are particularly adept at surviving freezing and persist under cold and low or nongrowth conditions.

Refrozen, sediment-laden ice-core samples from the subglacial environment in Greenland were recently obtained from the NorthGRIP borehole when pressurized, 'pink'-colored basal water at the base of the ice sheet entered the lower 45 m of the borehole and froze (Anderson et al., 2004; Figure 9). Before this discovery, the existence of large amounts of water at the base of the Greenland Ice Sheet was not anticipated. Although cell concentrations in this refrozen basal water were 10 times greater than in the overlying glacial ice (basal ice = 1.6×10^3 cells ml^{-1} , glacial ice = 1.6×10^2 cells ml^{-1} ; Christner et al., 2006), the basal material was extensively contaminated with the hydrocarbon fluid used for ice-core drilling, making conclusions about the microbiology of the subglacial environment tentative. This subglacial debris contains minerals (e.g., sulfides and iron, which produced the pinkish color) and organic material from the bedrock, which could fuel microbially mediated chemical weathering reactions (e.g., Tranter et al. (2002)) and support a community isolated from direct input from the surface. The data collected so far show that Greenland, like Antarctica, contains microorganisms within glacial ice and in the liquid subsurface environment.

Temperate Mountain Glaciers

Glacial ice cores from nonpolar, low-latitude glaciers in the Andes, Himalayas, and New Zealand generally contain more recoverable bacteria (i.e., colony-forming units) and a greater variety of species than those from polar ice cores (Christner et al., 2000; Christner et al., 2003; Foght et al., 2004; Xiang et al., 2005). This geographic difference is consistent with the closer proximity of mountain glaciers to locations with substantial vegetation and exposed soils, which serve as major sources of atmospheric particles. Despite great differences in the environments contributing biological particles to polar and nonpolar glaciers, phylogenetic analysis based on the phylogeny of small subunit rRNA sequences reveals that many of the bacteria characterized from different geographical locations belong to the same genera and possibly the same species (Priscu and Christner, 2004). One striking result from biological studies of ice cores is that there is no consistent, monotonic decrease in the number of recoverable bacteria with increasing age of the ice core (Christner et al., 2000). Rather, the numbers of recoverable bacteria at different depths appear to be a reflection of the prevalent climate and individual events that occurred at the time of deposition.

Figure 8 Scanning electron microscope images showing the relative amounts of particulate mineral and organic matter in a Vostok glacial ice core collected from 2779 m below the surface. Backscattered electron imaging was used to view the particles in panel (b); only mineral particles are detectable using electron backscatter. Organic particles not detected by electron backscatter are denoted by the yellow outlines in panel (a). The percentage of organic particles in ice cores below 1600 m, relative to the total particle count, is presented in panel (c) along with profiles of dissolved organic carbon (DOC). The positive relationship between particulate organic matter and DOC is shown in panel (d). DOC and scanning electron microscope methodology are described in [Priscu et al. \(1999\)](#).

Cells revived from ice-core samples have endured desiccation, high solar irradiation while at the surface, freezing, an extended period of frozen storage, and eventual thawing. Therefore, it is not surprising that a large number of the isolates recovered belong to bacterial groups that form spores (e.g., *Bacillus* and *Actinomyces*) or have thick cell walls and polysaccharide capsules. These structures would help overcome the stresses associated with water loss, namely, increased intracellular solute concentrations, decreased cell size, a weakened cell membrane, and physical cell rupture caused by freezing and thawing. The high frequency of pigment production in recovered isolates from temperate ice cores ([Christner et al., 2000](#)) is consistent with the need to absorb harmful solar irradiation, which can cause lethal DNA damage. Even though the surviving cells may have resistant structures and protective pigments, they must still incur some radiation and chemical damage during extended periods of inactivity. Long periods (30–180 days) of incubation were often necessary before visible colonies appear during culture efforts, yet the vast majority of the isolates could subsequently be subcultured to the stationary phase in <1 week. This observation indicates that time is required to repair accumulated cellular damage before growth and reproduction could begin.

A significant number of bacterial isolates characterized from a global range of ice cores are phylogenetically related to species recovered from Antarctic lake mats, sea ice, polar ice

cores, and other predominantly cold environments ([Priscu and Christner, 2004](#)). In terms of geographical differences between ice-core sites, *Bacillus* and *Paenibacillus* relatives of strains prevalent in soils were most commonly isolated from nonpolar glacial ices, and species of *Sphingomonas*, *Methylobacterium*, *Acinetobacter*, and *Arthrobacter* were ubiquitous and recovered from both polar and nonpolar ice-core locations. It is noteworthy that close relatives of the radiation-resistant type strains *Methylobacterium radiotolerans* and *Acinetobacter radioresistens* were also commonly isolated. The recovery of related microorganisms from many geographically diverse, but predominantly frozen environments, argues that these species probably have features that confer resistance to freezing and survival under frozen conditions.

Methods for Measuring Biotic Matter in Ice Cores

Particles in ice cores are typically measured on discrete core segments (usually at a depth resolution of several meters) using instruments based on the Coulter principle (e.g., [Delmonte et al. \(2004\)](#)). These investigations focused on the size, concentration, and source of the particles but failed to discriminate between biotic and abiotic forms, collectively referring to them as ‘dust’. Most of the data on the abundance of microorganisms in ice cores are from light microscopy, epifluorescence

Figure 9 Images of an ice core collected at a depth of ~ 3310 m from the NGRIP (Greenland) drilling site (Anderson et al., 2004). The ice core contains both colored frozen basal water and glacial ice (a). Low-resolution scanning electron micrographs of particles in glacial ice and adjacent frozen basal water are shown in b and c, respectively.

microscopy, and electron microscopy. Although these microscopic methods allow morphological and physiological characterization of the microorganisms, they are tedious and subject to large errors, particularly when cell density is low. Hence, microscopic analysis does not lend itself to high resolution, routine determinations of biogenic matter in ice cores.

Borehole optical loggers have been used successfully to quantify the *in situ* abundance of dust in several systems and modifications are underway to incorporate filter fluorimeters on the loggers to detect biota and biomolecules (Bay et al., 2005). Flow cytometers offer another promising method to detect and characterize biogenic matter rapidly in ice cores retrieved from selected sites. Flow cytometers were developed for use in the medical field to rapidly enumerate, characterize, and sort cells from blood and human tissues. More recently, they have been used to characterize viruses, bacteria, and phytoplankton in natural marine environments (e.g., Minor and Nallathamby (2004)). Flow cytometers examine particles in a focused stream of fluid directed individually in front of an optical beam. Morphological characterization and enumeration of the particles (biotic and abiotic) can be made by their light-scattering properties. The physiological properties of the microbial component of the 'dust' can be determined by either autofluorescence or fluorescence induced by the addition of specific fluorescence probes (Bay et al., 2005).

Autofluorescence or induced fluorescence allows microorganisms to be enumerated separately from abiotic particles, and can provide detailed physiological measurements such as DNA content, cell membrane integrity, and metabolic potential.

Our laboratory has begun to use flow cytometry to characterize particulate matter in ice cores from the Antarctic and Greenland. Importantly, these ice cores all followed strict preparation and decontamination protocols outlined by Christner et al. (2005) before cytometric analyses to ensure samples were not contaminated. A Microcyte™ flow cytometer was placed in a class 100 environmental chamber (less than 100 particles larger than $0.5 \mu\text{m}$ in each cubic foot of air space; equivalent to an ISO class 5 clean room), and calibrated with fluorescent beads of known size and fluorescence quantum yield. The fluorescent DNA probe Syto 60 (Molecular Probes Inc.) was added to melted ice cores, which were then incubated in the dark for 5 min before cytometric analysis. Forward light scatter was used to measure the size and abundance of the particles, while fluorescence counts discriminated the biotic from the abiotic particles in the samples. Initial tests on Vostok glacial (1686 and 2334 m) and accretion ice (3612 m) showed that counts of total particles and DNA-containing bacterial cells can be successfully determined (Figure 10). Data obtained from these samples by flow cytometry were verified by epifluorescence microscopy of samples stained with the DNA probe SYBR Gold and by scanning electron microscopy (Christner et al., 2005). Two previous studies have also employed flow cytometers to enumerate microbes in glacial ice cores. Karl et al. (1999) used a flow cytometer to show that there were $500\text{--}700 \text{ cells ml}^{-1}$ in Vostok accretion ice from 3,603 m, and Miteva et al. (2004) found concentrations of bacterial cells ranging from 6.1 to $9.1 \times 10^7 \text{ cells ml}^{-1}$ in ice cores taken from the GISP2 (Greenland) "silty" ice (~ 10 m above bed-rock). In both of these studies, as well as our own, small cells ($\sim 1 \mu\text{m}$) dominated the populations found within ice cores.

Metabolic and Evolutionary Potential of Ice-Bound Microorganisms

The question of whether the microorganisms in glacial ice are metabolically active has fundamental significance to both glacial microbiologists and geochemists. Microbiologists are most interested in the diversity, evolution, and survival mechanisms of microorganisms, whereas glacial geochemists are concerned that *in situ* microbial activity consumes or liberates trace gases, thereby affecting the absolute concentration and isotopic content of the gases under concern. If the gases within the ice core are significantly altered by biogenic activity, a reassessment of ice core paleogas records may be necessary (Campen et al., 2003; Sowers, 2001).

Priscu and Christner (2004) estimated that the polar ice sheets of Greenland and Antarctica contain a combined total of 9.6×10^{25} prokaryotic cells, which equates to 2.7×10^{-3} petagrams ($1 \text{ Pg} = 10^{15} \text{ g}$) of organic carbon. This value represents a previously unrecognized carbon pool and approaches the bacterial carbon contained in all surface freshwater on our planet (Whitman et al., 1998).

Paleoclimate studies have accurately dated layers within the ice caps of both Antarctica (Petit et al., 1999; EPICA, 2004) and

Figure 10 Flow cytometer data showing the relative abundance and size distribution of cellular and abiotic particles in Vostok glacial ice (a = 1686 m; b = 2334 m) and accretion ice (c = 3612 m). Cellular particles were characterized by their fluorescence induced with the DNA stain Syto 60. Red and blue symbols denote DNA-stained cells and abiotic particles, respectively.

Greenland (Alley, 2002), providing an important stratigraphic age record for these microbial ice repositories. This reservoir of ancient microorganisms, which can include fungi, bacteria, and viruses (Castello and Rogers, 2005), provides an unexplored frontier for the study of microbial variability over at least eight glacial cycles (~1 million yr). Data collected from selected habitats on our planet shows that microbial cells can be revived after extended entrapment in geological materials (Table 2). Willerslev et al. (2004a and b) further showed that DNA can remain viable for several million years in icy environments and concluded that natural ice provides an excellent repository for maintaining stable DNA.

A global assessment of prokaryotic diversity in glacial ice, based on 16S rRNA gene sequences, revealed that many of the isolates are related to psychrophilic (capable of growth at 5 °C or below, maximal temperature is approximately 15 °C and minimal temperature is 0 °C or lower) and psychrotolerant

Table 2 Reports of viable microorganisms retrieved from icy habitats representing a range of temporal isolation

Investigators	Location	Age (ka)
Sheridan et al. (2003); Miteva et al. (2004)	Glacial ice: GISP2, Greenland	120
Abyzov (1993); Christner et al. (2005)	Glacial ice: Vostok, Antarctica	420
Christner et al. (2003)	Glacial ice: Guliya, China	750
Shi et al. (1997)	Permafrost	3000

Figure 11 (a) Cross-polarized image of a Vostok accretion ice core from 3590 m below the surface showing the grain boundary between two crystals. (b) Microscopic view of the same vein following treatment with an epoxy resin, which highlights the grain boundary. The grain boundaries in polycrystalline ice, particularly where they form triple junctions, have been proposed as a site for life in solid ice (Price, 2000).

(capable of growing at 5 °C or below, with maximum growth temperature often between 25 °C and 30 °C) species originating from sites ranging from aquatic and marine ecosystems to terrestrial soils, with little in common except that all are permanently cold or frozen. The distribution of related species in geographically diverse glacial environments implies that members of these bacterial genera evolved under cold conditions and likely possess similar strategies to survive freezing and metabolize at low temperatures. This paradigm supports the contention of others (e.g., Price (2000), Campen et al. (2003), and Sowers (2001)) that the organisms are actually metabolizing in 'solid ice', presumably within grain boundaries (Figure 11). If microorganisms are indeed metabolizing and growing within the ice itself, a completely new set of selection pressures must be considered.

Rogers et al. (2004) postulated that selected pathogenic microbes survive and are recycled through ice in a process they call 'genome recycling' (Figure 12). Their contention is that organisms trapped in ice for hundreds of thousands to millions of years are eventually released when glaciers calve and the ice melts, allowing the flow of genetic material from trapped microorganisms to contemporary microbial populations. The mixing of ancient and modern genotypes may affect mutation rates, fitness, survival, pathogenicity, and other

characteristics through a change in allele proportions in the populations. Genome recycling is dependent on the revival and establishment of organisms once they emerge from the ice sheets and glaciers and transfer their genetic information to extant populations, which are then reincorporated into ice sheets and glaciers via eolian processes. Rogers et al. (2004) estimate that 10^{17} – 10^{21} viable microorganisms are released annually from melting glacial ice.

Castello et al. (2005) documented the recovery and identification of viable phage (a virus for which the natural host is a bacterial cell) from the bacterium *Bacillus subtilis*, and also have amplified genomic segments of tomato mosaic tobamovirus from ice cores assigned dates exceeding 100 ka BP. Our laboratory has

also observed free viral particles in both meteoric and accretion ice from the Vostok ice core (Figure 13), implying that viruses, like bacteria, are prevalent in glacial ice. These viral data, in concert with the concept of genome recycling proposed by Rogers et al. (2004), have led Smith et al. (2004) to postulate that glacial ice may provide a reservoir for pathogenic human viruses, particularly caliciviruses, influenza viruses, and enteroviruses. These viral groups occur in great abundance, are readily transported in the atmosphere, and may participate in ongoing disease cycles once released from the ice. Smith et al. (2004) contend that icy reservoirs may explain cyclic calicivirus events and the decades-long disappearances and subsequent reappearances of influenza-A subtypes. Although further research on ice cores is required, these preliminary data infer that viral reservoirs provided by glacial ice should be considered in eradication efforts for pathogenic human viruses.

Figure 12 General scheme of genome recycling through glacial ice proposed by Rogers et al. (2004). Organisms immured in the ice for millennia are eventually released as the glaciers calve or melt, releasing them to the environment where their genes can mix with contemporary gene pools. Organisms forming the new gene pools are eventually trapped as dust particles in the ice where they remain isolated until the next cycle begins. Courtesy of S. Rogers, Bowling Green State University.

Conclusions

Glacial ice covers a large portion of Earth and contains information of past climate extending back to at least eight glacial cycles. In addition to important records of paleoclimate, recent investigations have shown that glacial ice contains an important record of microorganisms on our planet that may provide new information on biogeochemical processes, microbial evolution and physiology, and biomedical information on pathogens that occurred during past glacial and interglacial periods. Data on the biological nature of ice cores also provides us with an important Earthly analogue for the study of life on Mars and other icy worlds.

General Concepts

Temperatures vary as a function of depth within the ice sheets. The temperature–depth profiles (symbolized $T(z)$, z being the common symbol for the vertical coordinate in glaciology) are controlled by surface climate, ice flow and thickness, and heat flow from the underlying crust (reviewed by Paterson (1994)). In the thick central regions of ice sheets, tens of millennia are required for the temperature at depth to adjust to major climate changes, including changes of surface temperature and snowfall rate. The $T(z)$, measurable as the temperature profile in boreholes, thus contains a legacy of climate history that is an important source of paleoclimate information. In particular, analyses of borehole temperatures yield the most convincing estimates for long-term averages of past surface temperatures at ice core sites, and hence for the magnitude of major transitions between persistent climate states (in particular the Wisconsin–Holocene transition, and the termination of the Holocene Climatic Optimum). The most comprehensive and accurate multimillennial reconstructions of temperature history in the late Quaternary are achieved by combining borehole temperature analyses with analyses of stable isotopes of ice and of gases (see review by Cuffey and Brook (2000)). Borehole analyses also yield an estimate for the geothermal flux, a parameter of great interest in studies of ice dynamics and tectonics.

The central reason for the value of the borehole thermometry method is that the measured variable, the temperature, is a direct remnant of the variable being reconstructed, not a proxy for it. The remarkable purity of the ice and absence of liquid flow at the deep core sites greatly assist the analyses; in this setting the heat flow problem is rather simple compared to that in most geologic media. The flow of the ice itself does introduce a major complication, but one that can be handled effectively and even used to advantage. Knowing the depth–age scale at the borehole site (from analyses on the ice core – see *Chronologies*) is the key to circumventing this problem, as it provides a strict constraint on the net displacement of ice layers over time (Cuffey et al., 1995). The ice flow then actually becomes beneficial because it increases the spatial wavelength of transient temperature signals, reducing their diffusional damping. Heat flow physics severely limits the time resolution of the borehole temperature reconstructions, and ensures that this resolution decreases drastically as one probes backward in time (Clow, 1992). The maximum possible time resolution varies substantially from site to site, but central Greenland provides a useful illustration of its general character; here the reconstructed temperature for ages of 0.2, 5, and 20 ka is an average over approximately 0.05, 1, and 10 ka, respectively.

As with many aspects of ice core analysis, borehole temperature reconstructions work best in the thick, cold, central ice divide regions of the ice sheets, where liquid water is negligible and horizontal flow is slow. Boreholes that are kilometers deep

are essential for gaining any information about the Wisconsin–Holocene transition. Analyses for sites with significant summer melt generation may be useful, but the impact of refreezing water on the energy budget confounds paleotemperature reconstruction (Paterson and Clarke, 1978).

Borehole temperature analyses specifically give information about the temperature of the ice sheet surface averaged over time. This is in contrast to the stable isotopes of ice, which are most strongly related to temperatures in the overlying atmosphere during condensation (see *Stable Isotopes*).

Heat Transfer in Ice

General Physics

The evolution of the $T(z)$ profile obeys the conservation of energy, and is calculated using the traditional heat equation (e.g., Paterson and Clarke (1978)). The rate of change of temperature over time at a given coordinate within the ice mass is governed by diffusion (the divergence of conductive heat fluxes), advection (heat transport by the moving ice), and heat generation due to the work of ice deformation (strain heating). The thermal parameters, the conductivity and heat capacity, are both temperature dependent (Yen, 1981). The thermal diffusivity for ice is approximately $10^{-6} \text{ m}^2 \text{ s}^{-1}$, implying the effective length scale for diffusive propagation of temperature signals over a time interval t is $0.001 t^{1/2}$, or roughly 200 m in 1 ka, and 600 m in 10 ka. The downward vertical ice flow governing heat advection is greatest at the surface and declines with depth in the ice sheet, to a value of zero at the bedrock interface. Characteristic values in the upper part of the ice column are comparable to the accumulation rate: decimeters per year in Greenland and West Antarctica, but only centimeters per year in dry East Antarctica (see *Dynamics of the Greenland Ice Sheet*, *Dynamics of the East Antarctic Ice Sheet* and *Dynamics of the West Antarctic Ice Sheet*). Advection and diffusion thus have comparable influence on the $T(z)$ in the former, but diffusion dominates $T(z)$ in the latter. The conditions in central Greenland and West Antarctica (both with ice 2–3 km in thickness) are fortuitously ideal for using borehole temperature analyses to probe the Wisconsin–Holocene transition and persistent trends within the Holocene.

Characteristics of Profiles

Ice sheets are effective thermal insulators, so the geothermal flux significantly warms the ice sheet bed relative to the surface. The temperature difference through the ice thickness is more than 50 °C in central East Antarctica, and more than 20 °C in central Greenland (Figure 1). In accumulation regions, the downward advection of cold surface ice reduces the temperature at all depths (Robin, 1955). In East Antarctica, this cooling

Figure 1 Measured borehole temperature profiles from Greenland and Antarctica: (a) The profiles through the entire ice thickness at three locations: Vostok Station, East Antarctica (Tsyganova and Salamatin, 2004), the GISP2 site, central Greenland (Clow et al., 1996), and Siple Dome, West Antarctica (Engelhardt, 2004). The GISP2 profile illustrates the strong cooling influence of vertical heat advection (see *Dynamics of the Greenland Ice Sheet*). Both Antarctic sites have much drier climate and the profiles are therefore conduction dominated (see *Dynamics of the East Antarctic Ice Sheet* and *Dynamics of the West Antarctic Ice Sheet*). Siple Dome is a warm site with relatively thin ice, located near the margin of the West Antarctic Ice Sheet, whereas Vostok is in the thick, cold interior of East Antarctica. (b) The upper portion of the GISP2 temperature profile, showing the remnants of past climates; cool ice centered at 1600 m depth reflects the last glacial climate, whereas warm ice centered near 700 m depth reflects the Holocene climatic optimum.

is quantitatively significant but does not cause the form of $T(z)$ to deviate much from the linear (Figure 1). In Greenland and West Antarctica, the advection is strong enough to make $T(z)$ strongly concave (Figure 1), with nearly isothermal ice in the upper half of the ice sheet above basal layers that warm strongly with increasing depth (Gow et al., 1968; Cuffey et al., 1995).

The paleoclimate signal in $T(z)$ is typically a small deviation of temperature from the steady profile, tenths of a degree Centigrade in magnitude. The borehole temperature measurements must therefore have high accuracy.

Measurement of the Temperature–Depth Profile

The thermal mass of fluid in a borehole is trivial compared to that of the surrounding ice sheet. Further, horizontal variations in temperature are negligible over kilometers. Thus, the temperature in a borehole accurately represents the temperature at same depth in the surrounding ice sheet, provided that the thermal disturbance from drilling has been allowed to decay, and that spontaneous convection of the borehole fluid is limited (Clow et al., 1996). In locations with very strong temperature gradients and relatively wide boreholes, it may be desirable to reduce such convection by inserting baffles.

The borehole temperature is measured using sensors, usually thermistors, suspended on a cable connected to a recording device at the surface. For the kilometers-long deep ice sheet boreholes, the great length of cable presents a major logistical challenge, as the winch system must be large and heavy, and hence difficult to deploy at remote locations. Proper circuit

design allows the electrical resistance of the long cable to be cancelled so that all of the instrumentation except the sensor can remain in a controlled environment at the surface, allowing for very accurate measurements. This is the design of the United States Geological Survey system (Clow et al., 1996), the best in the world, with an accuracy of more than 0.002°C . Less accurate, but nonetheless useful, measurements are made with circuits that attach to drill cables and use their communication wires to return numbers to the surface (e.g., Gow et al., 1968).

Where the fluid filling the borehole is liquid (as in all deep boreholes), the thermal contact between sensor and fluid is strong and the measurement can be made by steadily lowering the probe into the borehole, if a fast-response sensor is used. Otherwise, the sensor must be held at a given depth until equilibration with the surroundings, a time-consuming process.

The Inverse Problem

The goal of the ‘paleothermometry problem’ is to use borehole temperature measurements to infer the history of climatic surface temperature, effectively reversing nature’s heat flow process. This is a difficult problem of inverse theory (Clow et al., 1992; MacAyeal et al., 1993). One would like to simply use the mathematical description for temperature evolution and calculate backward in time to construct the answer. But this is essentially impossible because diffusion acts as an averaging process, so its reversal is unstable.

There are two distinct major problems. The first is that the time resolution of the answer is limited. The reconstructed temperature history cannot accurately represent the high-frequency content of the true climatic forcing, as the diffusion process removes this information by averaging. As an extreme example, this means that the method cannot reveal the magnitude of diurnal temperature cycles centuries or millennia in the past. More to the point, the method cannot be used to directly learn the magnitudes of the Dansgaard–Oeschger events (roughly a 1.5-ka period) or demonstrate that they are truly temperature changes. And for a climate transition (an abrupt increase in temperature, for example) the method cannot reveal its true rapidity; a warming spanning one decade and a warming spanning five centuries will be essentially indistinguishable a few millennia later. The second problem is that the inverse calculation can greatly magnify errors in the measurement of $T(z)$. Forcing a perfect match between model and measured $T(z)$ will always reconstruct a temperature history with unrealistic large and meaningless oscillations.

Successful temperature reconstructions use, in a variety of forms, one of two approaches for coping with the inherent difficulties of the analysis. First, one can impose limitations on the effective frequency content of the reconstruction, in accordance with the resolving power of the method for the available data at a given site. A simple way to impose such limitations is to reconstruct not a continuous temperature history but a small number of discrete temperatures representing mean values or extrema (e.g., Dahl-Jensen and Johnsen (1986)). The resolving power itself can be derived rigorously from numerical calculations of the influence of past impulsive

temperature forcings on the present $T(z)$ (MacAyeal et al., 1991; Clow 1992; Cuffey et al., 1995), but such results are seldom included in publications on borehole paleoclimatology. Second, one can force (MacAyeal et al., 1991) the temperature reconstruction to adopt some aspects of a specified climate history (called the preconception). This is referred to as ‘regularization.’ For example, the reconstruction can be made proportional to the ice isotopic time series (e.g., Cuffey et al., 1995 – see [Stable Isotopes](#)).

All methods for solving the inverse problem use the heat equation in conjunction with an ice flow model to calculate the modern $T(z)$ from a specified surface temperature history (this is the ‘forward problem’). This calculated $T(z)$ is then compared to the measured borehole temperatures, and the mismatch used to guide adjustments to the imposed surface temperature history. This process is repeated until an optimal surface temperature model is found. An ‘optimal’ model is one which minimizes a chosen performance index. This index contains a measure of the summed squares of mismatch between calculated and measured $T(z)$, and may include additional constraints (MacAyeal et al., 1991). The optimization itself can be achieved with a variety of methods, including iterative singular value decomposition, Levenberg–Marquardt minimization, and Monte Carlo analysis (the testing of a large number of possible solutions to compile a distribution of acceptable results). Application of control theory can maximize the efficiency of the optimization computation (MacAyeal et al., 1991).

The vertical heat advection is a crucial term in the forward calculations. Vertical flow rate is a function of ice sheet geometry, which evolves as a lagged function of changes in accumulation rate, ice margin position, and ice temperature (Paterson, 1994). The most complete analyses of borehole temperature are ones that perform simultaneous reconstructions of the surface temperature and accumulation rate histories, using borehole temperature data and the measured depth–age scale in conjunction with other information about ice sheet history (Cuffey et al., 1995; Cuffey and Clow, 1997).

Specific Strategies

Within this general framework, most borehole paleothermometry analyses use one of the following methodologies. Note that in all of these, the geothermal flux is found as part of the optimization, in addition to parameters characterizing the surface temperature history.

1. *Sparse reconstruction.* The reconstructed surface temperature history consists of a small number of optimized values, linked by simple interpolation to form a continuous function of time (e.g., Dahl-Jensen and Johnsen (1986) and Alley and Koci (1990)).
2. *Monte Carlo reconstruction.* A large number of temperature histories are found, by guided random perturbation, that predict the measured $T(z)$ to within uncertainties (Dahl-Jensen et al., 1998). Each of these histories consists of values at specified times, separated by an interval that increases back in time. The reconstructed surface temperature then consists of a frequency distribution of temperatures at each time.

3. *Spectral composite.* The reconstruction is a sum of periodic components, in which the contribution from higher frequencies is forced to decrease backward in time in accordance with the physical limitations on the resolution (Clow and Waddington, 1999).
4. *Isotopic calibration.* The reconstructed surface temperature history is proportional to the stable isotopic composition (see [Stable Isotopes](#)) of ice of a given age (Cuffey et al., 1995; Johnsen et al., 1995). In this case, the optimized parameters are not temperature values but rather sensitivity coefficients describing the magnitude of isotopic variation per variation in temperature (a single set of optimal values may be found for the entire history, or they may be allowed to change between specified intervals). The dominating influence of climatic temperature and its gradients on isotopic composition of polar precipitation justifies this method, *a priori*, on physical grounds; the isotopes are a strong correlate of temperature for thermodynamic reasons (Dansgaard, 1964; Cuffey and Brook, 2000). The connection of stable isotope records with temperature profiles was made first by Robin (1976), Johnsen (1977), and Paterson and Clarke (1978).

The risk with this method is that it may fail completely to provide an acceptable reconstruction if the isotopes are not in fact correlated with temperature. This has never proved to be a problem in the polar regions, however (Alley and Cuffey, 2001). The benefits of this method are considerable. It immediately generates an estimate for the climatic temperature variation at most frequencies, from periods of a few years to tens of millennia. The sensitivity coefficients themselves contain additional information about paleoclimate that is testable using climate models equipped with isotopic tracers. It should be remembered, however, that the method does not evaluate whether the high-frequency variations are accurately reconstructed or not; this must be done using some other method like gas isotopes (see [Thermal Diffusion Paleotemperature Records](#)).

Major Results

The achievements of borehole temperature analysis have increased significantly from the mid-1990s. Though valuable, older studies faced serious limitations (Weertman, 1968; Gow et al., 1968; Dahl-Jensen and Johnsen, 1986) because the ice core sites were chosen for logistical rather than scientific reasons, and because accuracy of the temperature measurements was not very high. This recency explains why no linked borehole–ice core studies comparable to those of central Greenland have yet been completed in central West Antarctica. Further, it was only in the early years of the twenty-first century that the gas isotopic methods for assessing rapid temperature changes became available (Severinghaus et al., 1998 – see [Thermal Diffusion Paleotemperature Records](#)). These provided compelling evidence that the borehole temperature-based isotope calibrations are quantitatively applicable to high frequency events.

Greenland

Analyses from central and southern Greenland (see [Greenland Stable Isotopes](#)) show that this region did experience a

Medieval Warm Period (culminating around AD 1000), a Little Ice Age cool period (AD 1500–1900), and warming to the mid-twentieth century (Alley and Koci, 1990; Cuffey et al., 1994; Dahl-Jensen et al., 1998). In contrast to some other regions of the Arctic, such as northern Alaska and Siberia, Greenland did not have renewed warming through the latter decades of the twentieth century. The Medieval Warm Period was approximately 1 °C warmer than present, and the Little Ice Age 0.6 °C cooler than present, in central Greenland.

These also reveal a persistent Climatic Optimum through the early–mid Holocene with temperatures at least 2 °C warmer than present (in central Greenland), terminating in cooling between 4 and 2 ka BP (Cuffey and Clow, 1997; Dahl-Jensen et al., 1998). All of these Holocene variations appear to have been larger in southern than in central Greenland (Dahl-Jensen et al., 1998).

The Wisconsin–Holocene deglacial transition was very large in central Greenland (Figure 2), at least 15 °C between the mean glacial climate and the mean Holocene, with the Last Glacial Maximum being at least 20 °C colder than present (Cuffey et al., 1995; Johnsen et al., 1995; Cuffey and Clow, 1997; Dahl-Jensen et al., 1998). Such extremely low surface temperatures appear to be consistent with the large expansion of continental ice sheets and sea ice extent during the glacial climate, coupled with the global reduction in atmospheric greenhouse gas concentrations.

The isotopic sensitivity across the deglacial transition was approximately 0.4 per mil $^{\circ}\text{C}^{-1}$ (when corrected for sea water composition changes), 0.25 per mil $^{\circ}\text{C}^{-1}$ across the mid–late Holocene cooling, and 0.5 per mil $^{\circ}\text{C}^{-1}$ at the termination of the Little Ice Age (Cuffey et al., 1995). These low values may be explained (see citations in Alley and Cuffey, 2001) by changes in the seasonal timing of precipitation, by the effects of evaporative recharge from nearby ocean surfaces, or by changes in

Figure 2 Reconstructed surface temperature history in central Greenland, from calibration of the isotopic record (see [Dynamics of the Greenland Ice Sheet](#)) and borehole temperature measurements at GISP2 (Cuffey et al., 1995), and the Monte Carlo reconstruction from borehole temperature measurements at GRIP (Dahl-Jensen et al., 1998), shown as the curves for plus/minus one standard deviation from the mean reconstructed temperature. The GRIP results are shifted to colder values for reasons that are not resolved but probably are related to a change in the deformation field deep in the ice beneath GRIP during the last deglacial transition (Marshall and Cuffey, 2000).

structure of cyclones. Some researchers have assumed that the isotopic sensitivity should be higher (>0.6 per mil $^{\circ}\text{C}^{-1}$) during the interglacial climate because there are fewer such correlated changes. This assumption is clearly contradicted by the available borehole temperature data (Cuffey et al., 1995; Dahl-Jensen et al., 1998).

The geothermal flux in central Greenland is approximately 50 mW m^{-2} (Dahl-Jensen et al., 1998).

West Antarctica

Analyses of a borehole at Siple Dome (Engelhardt, 2004) show that the geothermal flux is very high here ($\sim 70 \text{ mW m}^{-2}$). This is not surprising because the region is tectonically active, but it is very important because this heat source generates basal melt that lubricates the flow of ice streams draining West Antarctica (Paterson, 1994 – see [Dynamics of the West Antarctic Ice Sheet](#)).

East Antarctica

Temperature analyses for the deep boreholes in the dry interior of East Antarctica are challenged by the dominance of diffusional heat transport. The famous site at Vostok presents further challenges because it is not situated on an ice divide. Nonetheless, it has been shown here that the Wisconsin–Holocene deglacial surface temperature increase was greater than 10 °C and probably closer to 15 °C (Salamatin et al., 1998 – see [Antarctic Stable Isotopes](#)).

Holocene temperature changes have been examined using boreholes in thinner local flow centers close to the ice sheet margin. At Law Dome, the late Holocene features two thermal minima at AD 1250 and 1850, and a 0.7 °C temperature increase over the most recent 150 yr (Dahl-Jensen et al., 1999). At the dry Taylor Dome site, it appears that late Holocene temperature changes are anti-correlated with those from the Northern Hemisphere (Clow and Waddington, 1999).

Locations off the Main Ice Sheets

Borehole analyses from the much thinner ice masses apart from the great ice sheets have produced information about recent climate change. For example, a dramatic warming appears to have occurred in Svalbard during the twentieth century (Van de Wal et al., 2002).

Introduction

In the ideal case, the snow deposited on a glacier or ice sheet is buried by the following snowfall, building an undisturbed chronological precipitation record. After accessing this record by core drilling into this natural ice archive, one of the first and most important tasks is to establish the ice-core chronology as precisely as possible. How well this can be done depends strongly on the climatic and ice-flow conditions at the drilling site. In this article, only cold glaciers and ice sheets, with ice body temperatures constantly below freezing, are discussed. In these ice bodies, no mass is lost by internal melting. As ice is plastically deformed under its own weight, it is subjected to increasing thinning with depth and age (Figure 1). The upper 50–150 m of an ice sheet consists of consolidated snow, commonly referred to as ‘firn.’ Air is continuously trapped in the lower 10% of the firn (firn–ice transition), where interstitial pores around the firn grains are progressively closed off until the air is permanently isolated from the overlying atmosphere. Because the firn is permeable, the air above the firn–ice transition region can exchange with the atmosphere via diffusion and convection. As a consequence, the age of the air in a sample of an ice core differs from the age of the ice.

The main dating methods for ice cores are layer counting, ice-flow modeling, radioactive dating, and synchronization.

Layer Counting

Owing to the seasonal variation of temperature, sunlight, or atmospheric circulation, concentrations of many trace substances or isotopes show cyclic variations in ice cores (Figure 2). If these variations occur in a regular mode and are sufficiently resolved by measurements, annual layers can be counted back many thousands of years. Depending on the conditions in the ice (temperature, thinning of layers, etc.), variations are smoothed by diffusion or altered by chemical reactions. Diffusion is especially strong in the porous firn, where the transport is enhanced through the gas phase. The problem of diffusion, which is, for example, the predominant process in the case of water isotopes, can be corrected mathematically to a certain degree by a deconvolution algorithm (Johnsen, 1977), which extends the depth range for layer counting.

The classical method for tracing seasonal variations in ice cores is the ratio of the stable water isotopes $^{18}\text{O}/^{16}\text{O}$ and $^2\text{H}/^1\text{H}$. As this ratio is strongly affected by the condensation temperature, it reflects the seasonal variation of temperature. Seasonal variations are preserved beyond the firn–ice transition if the annual accumulation rate is at least 200 kg m^{-2} . In the consolidated ice, the self-diffusion of the water molecules is much smaller than diffusive transport in the firn, and seasonal variations in the water isotopes are preserved for many

thousands of years. Smoothing by self-diffusion is favored by thin annual layers (low accumulation rate, thinning by horizontal strain) and by high temperatures, for example, in the layers closer to bedrock, which are warmed by geothermal heat flux.

Trace substances are generally less affected by diffusion, especially when they are present in particulate form. Yet, there is always a lower limit of the annual accumulation rate, below which the annual variations are lost. One reason for this is that wind mixes the snow on the surface by scouring and relocation. Thus, annual layers are no longer preserved or are sometimes even missing. Another reason is that the annual variations are already smoothed to such a degree that when they are compacted to solid ice at the firn–ice transition, the deconvolution algorithm cannot reproduce an unequivocal record.

The best accuracy for layer counting is obtained by combining different tracers (Führer et al., 1993; Johnsen et al., 1992; Rasmussen et al., 2006). Ideally, the counting uncertainty is on the order of $\pm 1\%$.

Flow Models

Rheology of Ice

Ice is a non-Newtonian fluid with an empirical relation between strain rate $\dot{\epsilon}$ and stress τ , namely, $\dot{\epsilon} = A\tau^n$, known as Glen’s law (Glen, 1955). The coefficient A is temperature dependent, and the stress exponent n is on the order of 3 for intermediate stresses as they occur in glaciers. Given the knowledge of all material properties and boundary conditions, the plastic deformation of a glacier or ice sheet could be modeled. However, these boundary conditions and properties are generally poorly known. The bedrock topography is not resolved in sufficient detail, and past surface conditions (temperature, precipitation) can only be indirectly estimated. The same holds for the parameters that determine flow properties, such as ice temperature, crystal orientation, impurities, and basal sliding. Therefore, only rough ice chronologies can be constructed using only three-dimensional (3D) flow models.

For ice sheets, the so-called shallow ice approximation is often used: the ice flow is locally treated by simple shear, which allows calculation of horizontal flow velocities. With the assumption of a constant total ice thickness, the thinning function becomes very simple. The horizontal deformation profile has been approximated by Johnsen and Dansgaard (1992) with linear segments (Figure 3). The horizontal strain rate $\dot{\epsilon}_x = \dot{\epsilon}_{x0}$ is constant for the upper part of the ice sheet. Below is a shear layer of thickness h with horizontal strain rate $\dot{\epsilon}_x$ decreasing linearly, and the bottom of the ice sheet sliding with the velocity qv_{x0} , where v_{x0} is the horizontal flow velocity at the surface. The vertical strain ϵ_z is readily derived by observing continuity (x and z are horizontal and vertical coordinates,

Figure 1 Schematic cross-section through an ice sheet. Layers are stretched and thinned when sinking. The two darker layers comprise roughly the same number of annual layers.

Figure 2 Annual variations of stable isotopes (temperature proxy) and chemical trace substances (here, e.g., hydrogen peroxide (sensitive to sunlight)). Summers: red, winters: blue.

Figure 3 Johnsen–Dansgaard flow model: simplified horizontal flow velocity profile (thick solid line) for the location where the z -axis is drawn. A more realistic profile is indicated by the dotted line.

respectively, where z is zero at the bed rock and positive z point upwards):

$$\varepsilon_z = \begin{cases} 1 - k(H - z) & h \leq z \leq H \\ kz \left(q + \frac{1-q}{2h} z \right) & 0 < z < h \end{cases}$$

with

$$k = \frac{2}{2H - h(1 - q)}$$

where H is ice-sheet thickness (ice equivalent), and h is on the order of $H/3$ to $H/2$. The reported values for q are on the order of 0.15 (Johnsen and Dansgaard, 1992).

In the model, the ice becomes infinitely old at the base if no basal melting occurs, yet with annual layer thicknesses approaching zero. It is not known whether ice from the initial glaciation (30 Ma in Antarctica) is still present at the base of the large ice sheets, but two factors prevent the ice records from being extremely old: disordered ice flow due to roughness of bedrock topography, and basal melting. The oldest ice yet recovered from a continuous core is the one from Dome Concordia, Antarctica, with an estimated age of over 800 ka (European Project for Ice Coring in Antarctica (EPICA) Community Members, 2004).

Ice cores are often drilled on ice divides or local domes because of the relatively simple ice flow. At such sites, all ice retrieved in a core originates from snow deposited in the vicinity of the drill site. If the drill site is not located on an ice-divide, ice from deeper layers originates from snow that has fallen upstream of the drill site. Often, the simple approach can still be applied in such cases if one takes into account the upstream effect on the precipitation rate. In the case of long upstream trajectories and changing bedrock topography, the effect on thinning of the deeper layers can be handled only with a full flow model (Ritz et al., 2001). The same applies if variations in total ice thickness need to be taken into account. Yet, estimates show that the surface elevation of the polar plateaus has in general remained rather stable.

Special sites are the so-called domes, which are preferred drilling sites because of the expected large age of the ice near the bottom. These are places with zero surface velocity at the center of a divergent surface flow pattern.

Raymond Bumps

Underneath domes and divides, the effective deviatoric stresses are low and, because of the power-law dependence of strain with a stress exponent >1 , this situation results in a higher ice viscosity. Consequently, the deformation of the ice is slower, leading to upward arching of isochrones over the divide (**Figure 4**). These are the so-called Raymond bumps (**Raymond, 1983; Vaughan et al., 1999**). However, the importance of this effect depends on the thickness of the ice sheet, the accumulation rate, and the temperature (**Pettit and Waddington, 2003**). Raymond bumps are more important at divides of small ice caps, but less so for the large polar ice sheets.

Past Accumulation-Rate Estimates

If the thinning (vertical strain ε_z) at any depth is assessed with a model, then one can construct a chronology of the ice if past accumulation rates $a(z)$ are known:

$$\text{age}(z) = \int_z^H \frac{dz'}{\varepsilon_z' \cdot a(z')}$$

Past accumulation rates are often assumed to be proportional to the derivative of the mean saturation vapor pressure at the inversion layer with respect to temperature (**Jouzel et al., 1987**). The inversion layer temperature T_{inv} is related to the surface temperature T_s by $T_{\text{inv}} = T_{\text{inv}0} + c_1(T_s - T_{s0})$, where the index 0 refers to modern values. The mean surface temperature is estimated from the stable isotope ratio in the ice: $T_s = T_{s0} + c_2(\delta - \delta_0)$. c_1 and c_2 are constants and δ is the measured per mille deviation of the isotopic ratio $^2\text{H}/^1\text{H}$ or $^{18}\text{O}/^{16}\text{O}$ in the ice core relative to mean ocean-surface water, corrected for past changes in isotopic ratio and temperature. c_1 and c_2 result from calibrating the model with age reference points (**Schwander et al., 2001**).

An alternative approach for reconstructing paleo-accumulation rates is based on the concentration of trace substances in the ice. The net flux (atmosphere $\rightarrow$ ice) of any impurity is the product of the accumulation rate and the concentration in the ice. Past accumulation rates can thus be

computed by measuring the concentrations and estimating the past fluxes. By this means, **Wagner et al. (2001)** have assessed the accumulation rates for Central Greenland, using the cosmogenic radionuclides ^{10}Be and ^{36}Cl .

Optimized Combined Modeling

The estimate of past accumulation rates represents one of the largest uncertainties in ice-core chronologies. Other parameters that are often poorly constrained are basal melting, basal sliding, and upstream effects. In order to improve the accuracy of the age model, these poorly known parameters can be constrained by assigning a series of well-dated time horizons to corresponding depths. Such events include glacial terminations or minima of the Earth's magnetic field (see Section 'Age Horizons and Synchronization') that have been dated with best possible accuracy on other paleoarchives. It is sensible to assign the time horizons to within a certain tolerance (probabilistic approach). In order to guarantee a physically reasonable thinning and climatically realistic accumulation rate history, inverse modeling is used to match all time markers by searching the optimal parameters of combined ice flow and firn densification models. Mostly, this approach has been used for individual ice cores (**Parrenin et al., 2007**), with the consequence of leaving some discrepancies between different records, which must be considered carefully when investigating, for example, climatic phase lags between drilling sites. **Lemieux-Dudon et al. (2010)** have suggested an approach to reduce these chronology discrepancies by extending this method simultaneously to one Greenlandic (North Greenland Ice Core Project (NGRIP)) and four Antarctic ice cores (EPICA Dome C (EDC), EPICA Dronning Maud Land (EDML) Vostok).

Radioactive Dating

Small amounts of radioactive trace substances are incorporated in the ice, either as deposits in the snow or trapped in air bubbles during the transition from firn to ice. As ice is a very tight container for nearly all elements (exceptions are gases with small atomic radii, e.g., helium), inclusions in cold ice are extremely well preserved. Therefore, the age can be calculated from the radioactive decay law if the initial amount of radioactive material is known. Tracers used for radioactive dating of ice are given in **Table 1**.

Table 1 Radioactive isotopes used for dating ice cores

Isotope	Half-life (years)
^3H (tritium)	12.26
^{210}Pb	22.3
^{32}Si	172
^{39}Ar	269
^{85}Kr	10.77
^{14}C	5730
^{81}Kr	229 000
^{36}Cl	301 000
^{10}Be	1510 000
^{238}U	4 468 000 000

Figure 4 Raymond bump: isochrones arch up underneath ice divides and domes.

Fission Products

^{137}Cs , ^{90}Sr , ^{14}C , tritium, etc. resulting from nuclear weapons testing in the atmosphere during the 1950s and 1960s caused worldwide radioactive fallout and a twofold increase in atmospheric ^{14}C concentration, peaking in around 1963. This 'bomb peak' can be easily detected by total beta-activity measurements. It has often been used for a quick estimate of accumulation rates, allowing for a rough age scale for the firn layer.

^{210}Pb

^{210}Pb is a decay product of ^{222}Rn . Its half-life of 22 years makes it suitable to date relatively young ice. As the initial content of ^{210}Pb in snow is not very constant, the method is used only when no other dating options are available.

^{32}Si

A half-life of 172 years makes this isotope very suitable for dating historic age. But compared to other methods, it has never gained much importance because of its low and variable concentrations.

^{85}Kr , ^{39}Ar , ^{81}Kr

Gases are occluded in bubbles only at a certain depth, and the age of the air is less than the age of the ice. While ^{85}Kr has been used to date the air within the permeable firn layer (Schwander et al., 1993), ^{39}Ar would be appropriate to date the air below the firn-ice transition. However, its abundance is too small to obtain accurate ages of the air in the ice using conventional counting techniques (Loosli, 1983). This problem may be overcome by new techniques such as resonance ionization mass spectrometry or atom trap trace analysis, which could potentially extend the dating range for the occluded air using ^{81}Kr .

^{14}C

Ice contains carbon in the form of CO_2 in the bubbles and dissolved or particulate matter (dust, pollen). Because of the small amount of ^{14}C , only measurements with accelerator mass spectrometry (AMS) are feasible with the available amount of ice from core drilling. A few measurements have been done on 10-kg samples of 6–11-ka-old ice from the Dye3 core, with an accuracy of between 5 and 10% (Andree et al., 1986), which is significantly less than the accuracy of other methods.

Modern radiocarbon AMS dating can be done on very small samples, for example, a few hundred pollen grains (Vasil'chuk et al., 2005) and ultimately probably even on single larger pollen grains. The method has been successfully applied on organic carbon filtrates of as little as 5 μg from an Alpine ice core (Jenk et al., 2009).

For using ^{14}C for dating of ice, one must consider *in situ* production of ^{14}C by cosmogenic neutrons and muons, which interact with the oxygen of the water molecules (Lal et al., 1987; Van Der Kemp et al., 2002) yielding extra ^{14}CO and

$^{14}\text{CO}_2$. The amount of *in situ* produced ^{14}C depends on cosmic ray intensity, exposure time, as well as losses by diffusion and decay. The penetration depth of neutrons and muons in firn is a few meters and a few tens of meters, respectively. At low accumulation sites with firn depths of around 100 m, most *in situ* produced ^{14}C has time to escape to the atmosphere before bubbles are closed off (de Jong et al., 2004). Postcoring *in situ* production of ^{14}C may also be important, especially when ice cores are stored at high altitudes and latitudes, where the cosmic ray intensity is considerable.

^{10}Be and ^{36}Cl

These isotopes are produced by cosmic rays and modulated by solar activity and Earth's magnetic field. Except for the latest drilled ice cores from Antarctica, most ice cores that have been recovered so far are significantly younger than the half-life of these isotopes. Fluctuations in the initial contents limit the dating accuracy. Since both isotopes are produced and transported by similar mechanisms, one could expect that the initial $^{10}\text{Be}/^{36}\text{Cl}$ ratio should be rather constant, and that this ratio, with an apparent half-life of 376 ka, could be adequate for dating ice. However, even this ratio fluctuates by a factor of 2–5, probably because of the differential chemical behavior. Therefore, the main purpose of ^{10}Be and ^{36}Cl measurement on ice cores has been to study variations in solar activity and the Earth's magnetic field. However, in the case of disturbed layering of very old remnant ice near the bedrock, dating with these isotopes could provide rough estimates of the period during which ice was formed (Baumgartner et al., 1997).

Uranium Series

The measurement of ^{238}U and its daughter products has been used to determine the age of blue ice from Allen Hills (Antarctica; Goldstein et al., 2004), though with relatively large uncertainties. Daughter products in the ice originate predominantly from the recoiling out of dust particles into the ice after alpha decay. The amount of the daughters depends on the length of time the particles have been incorporated in the ice. Aciego et al. (2011) have significantly improved the method and validated it on well-dated ice samples from the Dome C ice core, and provided a first age estimate for the basal ice. The age range of the U-series method is limited to about 1 My, where the daughter products of ^{238}U approach equilibrium concentrations. The accuracy is about 10% for intermediate ages (200–500 ka).

Age Horizons and Synchronization

Since the uncertainty of direct absolute dating of ice is considerable (mainly due to the small amount of datable material), ice-core chronologies often rely on indirect dating, that is, by comparison with other better dated paleoarchives, including other ice cores. In the ideal case, the well-dated record is annually laminated (e.g., the marine sediments from the Cariaco basin (Hughen et al., 1998), or the lake sediments from Holzfelder Maar and Holzmaar (Zolitschka, 1998)). Unfortunately, these varved sediments are often affected by hiatuses or

do not extend to the present, but they can provide valuable information on the duration of climate events. Other archives are well suited to the application of absolute dating methods, such as U/Th-dated speleothems or corals.

The prerequisite for a correlation with ice-core records is that events occurring in the record are unequivocally assignable to a synchronous event in the dated record. Such events include volcanic eruptions, Milankovitch (orbital) variations, abrupt climate variations (Dansgaard–Oeschger (D–O) events), variations in the Earth’s magnetic field, variations in solar activity, or the impact of extraterrestrial objects.

Volcanic Eruptions

Acid precipitation (mainly sulfuric acid) from volcanic eruptions can easily be identified by electric conductivity measurements and ionic analyses. Large volcanic eruptions from the equatorial zone produce a global signal (e.g., Tambora, Indonesia, AD 1815; [Figure 5](#)). Volcanoes at higher latitudes usually produce only hemispheric signals (e.g., Laki, Iceland, AD 1873). Volcanic eruptions in the historic era have been used extensively to date younger ice with a 1-year accuracy and to determine mean modern accumulation rates ([Udisti et al., 2000](#)). Older volcanic eruptions are very useful for correlating different ice cores. However, the correlation between Northern and Southern ice cores has been successful only in a few cases, because correlation of the volcanic layers is often ambiguous. Potentially, ice cores can be synchronized by tephrochronology if volcanic layers can be attributed unequivocally to a specific eruption, for example, by its chemical signature ([Grönvold et al., 1995](#); [Narcisi et al., 2005](#)).

Tuning to Milankovitch Cycles

In the second half of the nineteenth century, James Croll proposed that the Pleistocene Ice Ages are caused by periodic changes in the Earth’s orbit around the Sun. These quasicyclic changes are a result of the gravitational interaction of the Earth with the Sun, the Moon, and the planets. Milutin Milankovitch improved the astronomical theory, leading eventually to the presently generally accepted causality between Earth’s orbital parameters and climate variations. Orbital computations have

been further developed, for example, by Berger and Laskar. The accuracy in absolute timing is about 1 ka in 1 My.

Tuning is accomplished by changing the chronology of a record such that its correlation with the target curve is increased (e.g., by maximizing the spectral power at the orbital bands). The target curve (e.g., total ice volume for tuning marine benthic $\delta^{18}\text{O}$ records) is calculated from the astronomical parameters (e.g., insolation at a given latitude) using a suitable model. A shortcoming of the method is the problem of over-tuning. For example, it has been shown that the spectral power at the Milankovitch band can be readily generated by tuning an arbitrary record of white noise. Recent orbital tuning work has therefore been as conservative as possible ([Karner et al., 2002](#); [Lisiecki and Raymo, 2005](#)). The uncertainty in the phasing between paleorecords and the astronomical cycles is on the order of 5 ka.

Ice-core records can be correlated to the Milankovitch cycles either directly or indirectly via synchronization, for example, with marine sediment records ([EPICA Community Members, 2004](#)). Direct tuning includes temperature-sensitive stable isotope ratios, the $\delta^{18}\text{O}$ of oxygen in the trapped air, and the O_2/N_2 ratio.

Stable isotope ratios (δD , $\delta^{18}\text{O}$) in precipitation reflect predominantly local temperature and are therefore directly climate sensitive ([Johnsen et al., 1995](#)). The oxygen in air bubbles ($\delta^{18}\text{O}_{\text{atm}}$) largely follows the $\delta^{18}\text{O}$ content of the ocean water and is thus a proxy for total ice volume, but it depends also on other aspects of the water cycle and biosphere productivity ([Landais et al., 2010](#)). The transfer from the ocean $\delta^{18}\text{O}$ to the air happens through the biosphere, with a time lag of about 2 ka and an offset of 23.5‰ (Dole effect). [Figure 6](#) shows the correlation between $\delta^{18}\text{O}_{\text{atm}}$ and Northern insolation ([Petit et al., 1999](#)). Because $\delta^{18}\text{O}_{\text{atm}}$ is a global parameter, it can also be used to synchronize the gas records of ice cores from both hemispheres. However, an even better candidate for this purpose is methane, because of its more distinct variations (see section ‘Abrupt Climate Variations’).

The O_2/N_2 ratio of the air extracted from the ice core is slightly less than the atmospheric ratio because O_2 is preferentially excluded at the firn–ice transition during the gas-trapping process. Additionally, there is usually some preferential loss of O_2 from the outer part of the ice core during storage. [Bender \(2002\)](#) has observed a high correlation between the O_2/N_2

Figure 5 The Tambora AD 1815 eruption recorded in the ice core from Dome C, Antarctica.

Figure 6 The $^{18}\text{O}/^{16}\text{O}$ isotope ratio of the air in the Vostok ice core correlating with the insolation at 65°N . The stable isotope ratio of the ice (δD) is a proxy for local temperature.

Figure 7 Correlation of the O_2/N_2 ratio with local insolation in the Vostok ice core.

ratio measured in the Vostok ice core and the local summer insolation (**Figure 7**). Bender assumes that the summer climate influences the physical properties of the firn grains, which eventually affects exclusion of O_2 at the firn-ice transition. Although the mechanism is not well understood yet, it is most promising because of the direct link with local insolation.

Abrupt Climate Variations

Abrupt warmings during glacial times (the so-called D–O events) are observed in the Greenlandic ice cores. Most probably, they reflect rapid changes in the thermohaline circulation, with reduced deep-water formation in the North Atlantic. Temperature increases of 10°C have occurred within decades. Such rapid events are therefore most suitable for synchronization with other paleorecords of similar sensitivity to these abrupt changes. Shackleton et al. (2004) have proposed a chronology for Greenland ice cores based on a correlation with planktonic $\delta^{18}\text{O}$ from a marine core taken from the Iberian margin off southern Portugal, which shows the same abrupt variations. D–O events are accompanied by abrupt variations of the atmospheric methane concentration. Since the mixing time of Earth's atmosphere is of the order of a few

years, these variations are observed in both hemispheres without considerable delay and are therefore ideal to synchronize the gas records from ice cores of the Northern and Southern Hemispheres (Blunier and Brook, 2001).

Variations of the Earth's Magnetic Field

The magnetic field of the Earth has undergone substantial variations in the past, including changes in overall strength, movement of the magnetic poles, and magnetic reversals. The Laschamp event, a prominent period with substantially reduced magnetic field intensity, centered around 41 ka BP. A weak magnetic field causes a lower shielding of the cosmic rays, thereby leading to an increase in cosmogenic production of radionuclides. Peaks in ^{10}Be and ^{36}Cl in polar ice cores have been found to coincide with the Laschamp event (Wagner et al., 2000).

Variations of the Solar Activity

The activity of the sun shows several quasicyclic variations. The most prominent one is the 11-year sunspot cycle (Schwabe cycle; half period of magnetic reversal) and the associated

22-year Hale cycle (full period of magnetic reversal). Other suggested cycles are Gleissberg (88 years), Suess (200 years), and Hallstatt (2.3 ka). There are also periods with exceptionally low solar activity (sunspot minima): these include the Dalton minimum (AD 1790–1820), the Maunder minimum (AD 1645–1715), the Spörer minimum (AD 1450–1550), and the Wolf minimum (AD 1280–1350). Changes in solar wind associated with changes in solar activity affect the magnetic field of the Earth and thus the production of cosmogenic radionuclides. The sunspot minima and the Schwabe cycle are clearly reflected in the ^{10}Be and ^{36}Cl content of ice-core records. Whether the 11-year cycle could eventually serve as a dating tool depends on the stability of its period, a question that is presently still open. An attempt to use the Schwabe cycle for dating has been made for the Tayler Dome ice core (Steig et al., 1998).

Impact of Extraterrestrial Objects

Impacts of large objects on the surface of the Earth are very distinct events and have the potential to be used as time horizons. Attempts have been made to find effects of the 1908 Tunguska Event. The term ‘Tunguska Event’ refers to a cosmic phenomenon observed on 30 June 1908 in Central Siberia over the Krasnoyarsk Territory, Irkutsk Region, when a large forest area was destroyed by the impact of a stellar object. The search for traces of iridium in a Greenland ice core from a large meteorite impact that may have caused the Tunguska event has failed (Rasmussen et al., 1995).

Age Scale for the Air Occluded in the Ice

The upper 50–120 m of an ice sheet is made of consolidated snow (firn) which is permeable to air (Figure 8). Air occluded at the firn–ice transition is therefore substantially younger than the ice. This age difference can be estimated with densification/diffusion models (Schwander et al., 1997). The air at the firn–ice transition is on the order of one to a few decades. The age of the ice at the firn–ice transition spans a larger range of a few tens to several thousand years under present conditions, mainly depending on temperature and accumulation rates. Locations with high accumulation rates and relatively high annual temperatures show the smallest ages, while sites in central Antarctica with accumulation rates of few centimeters per year show the largest ages. The difference between the age of the ice and air has not remained constant over time. Under glacial conditions, this age difference was generally several times larger than at present.

In ice-core records with sharp climate transitions (e.g., D–O events), the age model for the air can be verified by comparing $\delta^{15}\text{N}$ of the air with $\delta^{18}\text{O}$ or δD of the ice. Both $\delta^{15}\text{N}$ and the stable isotopes of the ice are sensitive to temperature. $\delta^{15}\text{N}$ is fractionated in the firn by thermal diffusion and records fast temperature changes with a short delay in the air trapped at the firn–ice transition, while the stable isotopes of the surface snow are direct proxies for the temperature. Thus, temperature changes are quasimultaneously recorded at two different depths. This depth offset can be reconstructed with the ice-thinning model for rapid climate changes in the past, and can

Figure 8 Firn layer of polar ice sheets: typical modern range of density and age for the top 150 m. Air bubbles are normally closed off in the density range 800–840 kg m⁻³.

be used to validate the firn models (Lang et al., 1999; Severinghaus and Brook, 1999).

Introduction

Analyses of air bubbles extracted from selected polar ice cores are an accurate and straightforward method of reconstructing the evolution of atmospheric CO₂ concentrations over the past few hundred thousand years. Only ice cores from locations where summer melting can be excluded are suited for such analyses. The reproducibility, determined by measuring the CO₂ concentration on closely neighboring samples of the same ice core, is between 1.5 and 3 ppm, depending on extraction and analytical methods, but also on origin and depth of the ice cores. However, the accuracy of the measurements could be slightly affected by the production or depletion of CO₂ in the air bubbles, as will be discussed in the last section. By comparing CO₂ records from ice cores from different drilling sites with different impurity concentrations and different surface temperature at the drilling site, it can be estimated that the uncertainty is below about 5 ppm. Meanwhile, progress in the analytical techniques to measure $\delta^{13}\text{C}$ of CO₂ has been made in recent years, reducing the analytical uncertainties to 0.05–0.07‰. $\delta^{13}\text{C}$ –CO₂ allows further investigations of the processes responsible for atmospheric CO₂ variations.

Antarctic ice core records presently reach an age of 800 000 years BP (before present, where present is normally defined as 1950) (Jouzel et al., 2007). Air gets enclosed in bubbles at the firn–ice transition at 70–120 m depth below the surface, depending on temperature and accumulation rates. This means that air in the bubbles is younger than the surrounding ice by a few decades for high accumulation drilling sites, and up to more than 5000 years for low accumulation drilling sites. For a given drilling site the age difference varies with temperature and accumulation rate changes in the past. Locations, surface temperature, and accumulation rates for some ice core drilling sites are given in Table 1.

The enclosure of bubbles occurs gradually in a depth interval of about 10 m. The mixing of air in the firn and the gradual enclosure process are responsible for the fact that the air in an ice sample does not have a well-defined age, but rather represents a mixture of atmospheric air within a certain age range. The possible time resolution depends on temperature and especially on annual accumulation rates. In ice cores from high accumulation rate sites the time resolution is only a few years, but very long ice core records are only available from low accumulation drilling sites, where the time resolution is less precise. For the EPICA (European Project for Ice Coring in Antarctica) Dome C ice core it was shown that a deviation of a gas concentration lasting 150 years is still detectable but its amplitude is reduced to about 50% of the original. Indirect CO₂ measurements from $\delta^{13}\text{C}$ in peat and stomatal density and stomatal index measurements on fossil leaves have a better time resolution and suggest century or even decadal variations of atmospheric CO₂ concentration in certain time intervals.

However, it was shown that despite the limited time resolution of the Dome C record, it would still detect the reported short-term fluctuations of the stomatal records (Blunier et al., 2005). The discrepancy can, therefore, not be explained by the time resolution of ice core CO₂ records.

In this article, CO₂ records of different time intervals, starting with the last millennium, are presented and discussed in individual sections. Where available, results from CO₂ isotope measurements ($\delta^{13}\text{C}$) are also included. Analytical methods and possible natural artifacts are discussed in the last two sections. Most of the CO₂ data presented in the different figures can be found on the website of the World Data Centre for Paleoclimatology: <http://www.ncdc.noaa.gov/paleo/data-list.html>. The CO₂ concentration is given in ppm (parts per million), which refers to the mole fraction of CO₂. $\delta^{13}\text{C}$ of CO₂ is reported as per mil values relative to Vienna Pee Dee Belemnite (the international reference material).

The Last Millennium

Continuous direct atmospheric CO₂ concentration measurements started in 1958. For earlier times, our knowledge about the development of the atmospheric concentration depends on the ice core archive and air in the firn, the top open porous layers of an ice sheet. The general trend based on various ice core records shows a consistent picture of an almost constant level of the concentration during the first eight centuries of the last millennium, of about 280 ppm, followed by the dramatic anthropogenic increase during the last two centuries. Ice core, firn air, and atmospheric measurements overlap smoothly as shown in Figure 1. Results from Greenland ice cores, shown with gray symbols, diverge from results from Antarctic ice cores with significantly higher values especially in the first six centuries.

The higher values are considered to be an artifact due to higher temperatures and higher impurity concentrations in Greenland ice cores. Due to these artifacts, only results from Antarctic ice cores are discussed in the following.

Law Dome firn and ice core measurements (Etheridge et al., 1996) cover the entire time period from AD 1000 and overlap with instrumental measurements. The reproducibility from these CO₂ results is 1.2 ppm, and the individual results represent a short-time interval due to the high accumulation rate at the coastal Law Dome. The record suggests an increase from about 279 ppm at the beginning of the millennium to about 282 ppm at AD 1100, relatively constant concentration until about AD 1600, followed by a decrease to a concentration of 277 ppm which lasted for about one and a half centuries. These natural variations are very important for our understanding of the carbon cycle. However, Law Dome is a coastal site with a relatively high surface temperature of –22 °C and the

Table 1 Characteristics of important ice core drilling sites

Drilling site	Coordinates	Surface temperature (°C)	Accumulation rate (kg m ⁻² year ⁻¹)
Byrd Station	79°59' S, 120°01' W	−28	160
Vostok	78°28' S, 106°48' E	−57	22

Figure 1 CO₂ concentrations and $\delta^{13}\text{C}$ of CO₂ from various Antarctic sites over the last millennium. The results from the Greenland ice core (gray triangles; Barnola et al., 1995) are considered to be too high due to the production of CO₂ in the ice. The solid line represents direct CO₂ concentration measurements on atmospheric air from the Mauna Loa (Tans and Keeling).

impurity concentrations are larger compared to drilling sites from the Antarctic Plateau. This and the fact that older, low-resolution Antarctic records were not able to confirm the small variations in the Law Dome record triggered remeasuring the last millennium CO₂ variations on an inland ice core. Recently, new detailed measurements along the EPICA Dronning Maud Land ice core confirmed the Law Dome record if the smoothing due to the lower accumulation rate is taken into account (Siegenthaler et al., 2005a; Figure 1).

It has been suggested that the lower values between AD 1600 and 1750 are related to the so-called Little Ice Age. However, it would be surprising if this climatic event, with a globally very small temperature anomaly, would have exerted such a distinct effect on global atmospheric CO₂ concentration. The Dronning Maud Land record strongly supports the variations suggested by the Law Dome record, but it does not constitute a final proof.

Over the past 200 years the $\delta^{13}\text{C}$ record of atmospheric CO₂ (Francey et al., 1999) is drifting to lighter values in parallel to the anthropogenic CO₂ increase. This reflects the input of isotopically light carbon into the atmosphere by the use of fossil fuel and deforestation with $\delta^{13}\text{C}$ values of about −30‰ and −25‰, respectively.

The Holocene

Two high-resolution CO₂ records exist that cover the entire Holocene. The Taylor Dome ice core from coastal Antarctica was drilled 1993/94. The Holocene section is found from about 120 to 350 m depth. A total of 417 samples from 69 different depth levels have been measured on this ice core (Indermühle et al., 1999). The Taylor Dome results have been confirmed by measurements along the EPICA Dome C ice core drilled on the East Antarctic plateau (Flückiger et al., 2002). A total of 700 samples from 117 different short-depth intervals have been measured between 99 and 416 m depth below surface. The two CO₂ records from Taylor Dome and Dome C are in good agreement, after the age scales are synchronized based on the CO₂ results (Monnin et al., 2004). Both records are shown versus the synchronized time scale (Figure 2).

The records show that the carbon cycle was not in a steady state during the Holocene. CO₂ concentrations decrease from 268 ppm at 10 500 years BP to 260 ppm at about 8200 years BP. The decrease was followed by an almost linear increase from 260 ppm to about 280 ppm at the beginning of the last millennium.

Figure 2 CO₂ data spanning the Holocene from Taylor Dome and Dome C and $\delta^{13}\text{C}$ data from Dome C. Data are plotted against the age scale of Dome C after the Taylor Dome record was synchronized with the one from Dome C, based on the CO₂ records (Monnin et al., 2004). The error bars characterize 1σ uncertainties. In black Antarctic CO₂ data over the last millennium from Figure 1 are plotted together with the atmospheric data from Mauna Loa. Note that other than in Figure 1 the $\delta^{13}\text{C}$ record stops before the anthropogenic change.

Without further information it is difficult to interpret the CO₂ record. Fortunately, it has been possible in recent years to finally obtain reliable $\delta^{13}\text{C}$ data over the Holocene (Elsig et al., 2009). The main features of the EPICA Dome C $\delta^{13}\text{C}$ record are an almost linear increase from -6.58‰ to -6.33‰ from 11 to 6 ka BP and a small decrease of 0.05‰ after 6 ka BP. This data revises earlier low-resolution data from Taylor Dome showing higher isotope variability over the Holocene.

The main sources and sinks of atmospheric CO₂ on a millennial time scale are the terrestrial biosphere and the ocean. Carbon in the terrestrial biosphere is significantly depleted in the heavy carbon isotope ^{13}C , while oceanic processes like carbonate compensation or coral reef growth have small fractionations versus atmosphere.

The increase of $\delta^{13}\text{C}$ to 8 ka BP can be explained by the growing terrestrial biosphere after the Ice Age. The Holocene record as a whole is seen as a combination of terrestrial uptake and changes in the marine carbonate cycle (Elsig et al., 2009).

It has been suggested that the CO₂ increase from 8 ka BP is related to emissions from early human activities related to land-use change. A release of terrestrial carbon should have led to a depletion of the atmospheric $\delta^{13}\text{C}$ values. However, the data reveals that this is not the case, strongly arguing against such a scenario (Stocker et al., 2011).

The Transition from the Last Glacial Epoch to the Holocene

The transition from the last glacial epoch to the Holocene (Termination I) was accompanied by an increase of atmospheric CO₂ concentrations of about 40%. This large, naturally induced CO₂ increase was observed by analyses of the first two ice cores reaching bedrock in Greenland and Antarctica: Camp Century and Byrd station. However, measurements on more recently drilled cores taken from more suitable drilling sites provide better core quality and improved analytical techniques. Thus, the newer sites have yielded more reliable and more detailed results concerning changes in atmospheric CO₂ concentrations during this transition.

Four hundred and thirty-two samples from 72 different short-depth intervals have been measured from the EPICA Dome C ice core, in a core interval between 350 and 580 m depth, covering the period 22 000–9000 years BP. The increase in CO₂ concentration from a mean value of 189 ppm between 18 100 and 17 000 years BP to a mean value of 265 ppm between 11 100 and 10 500 years BP, occurred in four clearly distinguishable intervals (Figure 3; Monnin et al., 2001).

The CO₂ increase starts at about 17 000 years BP and is almost linear in interval I. In interval II the rate of increase is reduced, but at the end of the interval a sudden increase of about 8 ppm is observed. During a cooling in Antarctica, the Antarctic cold reversal, the CO₂ concentration decreases slightly. In interval IV the increase continues at about the same rate as in interval I. At the end of the interval a sudden increase is observed again.

At the end of the last glacial epoch temperature increased in Antarctica and Greenland, but the magnitude and especially the evolution is quite different as shown (Figure 4). The CO₂ increase follows in its general trend more closely the temperature increase in Antarctica, suggesting that the Southern Ocean played a key role causing the CO₂ increase. However, the sudden increases at the end of interval II and IV coincide with sudden temperature increases in Greenland, indicating a significant influence of the northern hemisphere as well.

The start of the CO₂ increase is delayed by 800 ± 600 years (Fischer et al., 1999; Monnin et al., 2001), compared to the temperature increase at Dome C. This small delay, compared to the transition period of 6000 years, does not call into question the important amplification effect of the CO₂ increase for global warming during this climatic transition.

There are many suggestions for the possible causes of the CO₂ increase. The main suggestions are:

- Reduced solubility of CO₂ in the Southern Ocean surface waters due to a temperature increase synchronous with the one observed from Dome C.
- Enhanced air–sea exchange around Antarctica due to a reduced sea ice extent, leading to an increase in deep sea ventilation.
- Decreasing bioactivity in the Southern Ocean due to a reduction of aeolian dust deposition, leading to reduced iron fertilization.
- Effects in connection with the sudden temperature increases in the North Atlantic region connected with changes in deep water formation in the North Atlantic.

Figure 3 CO₂ and $\delta^{13}\text{C}$ record spanning the transition from the last glacial epoch to the Holocene, compared with temperature proxies from Antarctica (Dome C) and Greenland. The four intervals are discussed in the text. The error bars characterize 1σ uncertainties.

The section of ice discussed above has been remeasured for CO₂ by a different laboratory, using a different analytical method (Lourantou et al., 2010b). The agreement between the CO₂ data discussed above and this new dataset is remarkable ($R^2=0.996$). The new measurements also included analysis of $\delta^{13}\text{C}$ of CO₂, significantly increasing the handful of data points over the last glacial–interglacial transition previously available. The extended data from Dome C (Lourantou et al., 2010b) are generally in agreement with older data from the Byrd station (Leuenberger et al., 1992) and Taylor Dome (Smith et al., 1999) ice cores. The new results show a complicated w-shape pattern over the transition from glacial to interglacial. Despite the progress in $\delta^{13}\text{C}$ analyses and the increasing amount of available data, it is not currently possible to quantify the contribution of the potential causes presented above to explain the observed 76 ppm increase in atmospheric CO₂ concentration. A reasonable guess is that all four causes contributed to the increase, counterbalanced to some extent by the uptake of the growing terrestrial biosphere.

Initial investigations comparable to the ones presented above for Termination I have been made over the previous glacial–interglacial transition (Termination II). Compared to Termination I, the exact pattern and absolute size differ for both, the CO₂ concentration increase and its $\delta^{13}\text{C}$ variations.

However, they are attributed to the same main processes discussed above although individual contributions and timing vary due to the complex nature of climate–carbon cycle interactions (Lourantou et al., 2010a).

The Last Glacial Epoch

Drastic climatic variations on the millennial scale in Greenland and surroundings are characteristic for the last glacial epoch. They are related to variations in deep water formation in the North Atlantic. These variations have parallels in the Antarctic, but the amplitudes of the temperature variations are much smaller and they are not in phase with the ones in Greenland. Are there variations in atmospheric CO₂ concentration either synchronous with those in Greenland or with the Antarctic temperature variations? – Greenland ice core records are not well suited for the reconstruction of atmospheric CO₂ concentrations. Therefore, this question could only be answered after it became possible to synchronize the age scales of different ice cores through comparison of methane variations. A first reconstruction based on the comparison of the Byrd with the Greenland Ice Core Project (GRIP) Summit ice core records showed that there are variations in the CO₂ concentration on the order

Figure 4 Comparison of CO₂ variations during the last glacial epoch with proxies of Antarctic and Greenland temperatures. CO₂ measurements from the Byrd station ice core (gray circles, Stauffer et al., 1998; red dots, Ahn and Brook, 2008) and the Taylor Dome ice core (black open triangles). The error bars for the new Byrd station data characterize 1 σ uncertainties. The time scales for temperature proxies ($\delta^{18}\text{O}$ of the precipitation water) from the Greenland GRIP core and the Byrd station core have been synchronized by methane data. The green dashed lines mark rapid temperature changes in Greenland with a correspondence in Antarctica.

of 20 ppm (Stauffer et al., 1998). This finding was confirmed by measurements taken from the Taylor Dome ice core (Indermühle et al., 2000). The 1968 Byrd core has been remeasured and extended in higher resolution and better precision (Ahn and Brook, 2008). The Byrd and Taylor Dome records are presented in Figure 4 together with stable isotope records from Antarctica (Byrd ice core) and Greenland (GRIP ice core). The Greenland and Antarctic records have been synchronized by methane data (Blunier and Brook, 2001).

CO₂ variations mirror Antarctic temperature oscillations during the last glacial. In detail, the CO₂ excursions are related to the longer Greenland interstitials with a prominent Antarctic counterpart. In general, the CO₂ concentration increases in parallel to the Antarctic temperature, but its decrease is slower, starting 1–2 millennia after the temperature has started to decrease. This may be a consequence of a reduced/increased North Atlantic Deep Water (NADW) formation resulting in a reduced/increased stratification of the southern ocean leading to a release/uptake of CO₂ (Ahn and Brook, 2008). Alternatively, the Antarctic temperature variations are accompanied by drastic variations in the nonsea salt calcium deposits (nss Ca²⁺) originating from aeolian dust, so that the iron fertilization by such dust deposits in the Southern Ocean varied considerably. This variable level of fertilization could be responsible for the variations in atmospheric CO₂ concentration. Because the amplitude of nss Ca²⁺ variations during the last glacial epoch were of a similar magnitude as the decrease at the end of the last glacial epoch, it was concluded that the iron

fertilization change during the transition and, therefore, the biological activity in the Southern Ocean could at most be responsible for 20 ppm of the total 76 ppm increase of the CO₂ concentration (Röthlisberger et al., 2004) at the end of the last glacial epoch.

Besides an Antarctic imprint the CO₂ record also shows features which seem to be directly linked to events in the Greenland. As during Termination I it is observed that at times of rapid temperature increases in Greenland the CO₂ concentration raises on the order of 10 ppm. This effect is seen accompanying Dansgaard–Oeschger (DO) events 21–19. There may be a link to higher sea level stands during this period opposed to later in the glacial. The observed drop in the mean CO₂ concentration at the end of DO 19 may also be related to a drop in sea level stands or potentially to a rapid increase of dust flux in the equatorial Pacific and Antarctica around that time (Ahn and Brook, 2008).

CO₂ Records over Eight Glacial Cycles

In 1998, the ice core drilling at Vostok reached a depth of 3623 m. The stratigraphy is undisturbed down to a depth of 3310 m, and the ice at this depth has an age of about 420 000 years. The records cover, therefore, about four glacial–interglacial cycles. There is a close correlation between the CO₂ record and the $\delta^2\text{H}$ record of precipitation water which is a proxy for the Antarctic temperature, confirming

the clear interplay between this important greenhouse gas and climate (Petit et al., 1999).

The record shows that the main trend of atmospheric CO₂ levels is similar for each glacial cycle. During glacial–interglacial transitions the concentrations rise from about 180 to 300 ppm. The increase is about synchronous with the temperature increase, but the start of the CO₂ increase probably lags the beginning of the temperature increase by a few centuries (Caillon et al., 2003; Fischer et al., 1999). The decrease in CO₂ concentration at the end of an interglacial is slower than its previous increase and it lags the temperature decrease by up to several thousand years (Fischer et al., 1999).

The EPICA Dome C ice core drilled to a depth of 3260 m (EPICA Community Members, 2004) extends the Vostok record. Analyses on a wide range of constituents have been performed down to a depth of 3190 m, at which the age of the ice is estimated to be about 800 000 years old. Below 3190 m, the stratigraphy becomes disturbed once again. The Vostok CO₂ record back to 420 000 years BP (Petit et al., 1999) and the Dome C record from 420 000 to 800 000 years BP (Lüthi et al., 2008; Siegenthaler et al., 2005b) are shown compared with the $\delta^2\text{H}$ record of the EPICA Dome C core (Figure 5). The CO₂ records show that atmospheric CO₂ concentration was never higher than 300 ppm during the past 800 000 years, compared to a modern concentration of 390 ppm (2010). During interglacial epochs before 450 000 years BP, showing lower mean temperature but longer duration, CO₂ concentration was also lower. This is further evidence for a close relation between global, climatic cycles, and atmospheric CO₂ variations.

Analytical Methods

To measure the CO₂ concentration of air enclosed in air bubbles of polar ice samples, the air has first to be extracted and then analyzed in a second step.

Most laboratories are using a dry extraction method to extract the air, in order to avoid any interaction of melt water

with ice included carbonates potentially resulting in the production of surplus CO₂. Air bubbles can either be opened mechanically by cracking, milling, or grating ice samples or be released by sublimation of the surrounding ice.

One method is to crack ice samples of about 10 g in a needle cracker which is cooled to -30°C and evacuated after the ice was filled to the cracker. The escaping air from the opened bubbles directly expands over a cold trap into the absorption cell of a laser absorption spectrometer. The infrared laser is tuned several times over the absorption line of a vibration–rotation transition of the CO₂ molecule to determine the concentration (Indermühle et al., 1999). A variant of this technique uses gas chromatography and a cryogenic trapping step (Ahn et al., 2009).

A second method is milling ice samples of about 40 g in a kind of ball mill. The ice sample and stainless steel balls are placed in a small container which is evacuated and then shaken. Temperature during shaking is kept at -50°C to keep water vapor pressure low. Air is released directly to the inlet system of a gas chromatograph (Barnola et al., 1995).

A third method (Etheridge et al., 1996) is to place ice samples weighing 500–1500 g in a vacuum-tight stainless steel container with a kind of stainless steel ‘cheese grater’ inside. By shaking the closed container after evacuation, the ice is grated in small pieces. The escaping air is extracted by condensation at -255°C in an electropolished stainless steel trap. The extracted air is analyzed with a gas chromatograph. The advantage of this method is that the extracted air is not exposed to moving metal parts. For many measurements the large sample size is a disadvantage, but if enough ice is available and does not restrict the desired depth resolution, it has the advantage of having a very small analytical uncertainty (1σ error of 1.2 ppm).

A fourth method applied (Gürlük et al., 1998; Schmitt et al., 2011) is based on the sublimation of an ice sample below the triple point of water. This guarantees a high extraction efficiency of close to 100% which cannot be achieved by the mechanical dry extraction methods. As long as all air is enclosed in bubbles the extraction efficiency is not crucial.

Figure 5 CO₂ records from Vostok back to 430 000 years BP (black line) and from Dome C from 430 000 to 800 000 years BP (gray line), compared with the $\delta^2\text{H}$ record from Dome C (EPICA Community Members, 2004), a proxy for Antarctic temperature.

However, at great depth in the ice sheet the pressure is high and air becomes enclosed in clathrates. Clathrates are a crystalline, cage-like structure formed by water molecules, with air molecules trapped in the cages. If air is enclosed partly in bubbles and partly in clathrates, a fractionation of different air components may occur if the extraction is not complete. With the high extraction efficiency achieved by the sublimation technique such fractionation is avoided independent of how the air is trapped in the ice (i.e., in bubbles, enclosed in clathrates or even dissolved in ice). A small disadvantage might be the fact that this technique is more time-consuming than the mechanical ones.

For bubbly ice, no difference has been observed between results derived by the mechanical and the sublimation method. The reproducibility (1σ) for the sublimation method using about 30 g of ice is ~ 2 ppm for CO₂ and very good precision of around 0.05‰ is achieved for the analysis of $\delta^{13}\text{C}$ of CO₂ (Schmitt et al., 2011). For the mechanical methods, the precision for bubbly ice can be as low as 1.5 ppm for CO₂ and around 0.07‰ for $\delta^{13}\text{C}$ using ice samples of around 8 g and 5–6 g, respectively (Elsig et al., 2009; Lüthi et al., 2008).

Reliability of CO₂ Data from Ice Cores

The CO₂ records from several ice cores overlap with direct atmospheric measurements and show good agreement. However, this is no guarantee that the CO₂ concentration in air bubbles from older ice reflects exactly the true atmospheric CO₂ at the time of ice formation. The following processes could alter the CO₂ concentration in air bubbles of ice:

- CO₂ could be produced by chemical reactions of impurities contained in the ice (e.g., acid-carbonate reaction or oxidation of organic compounds).
- CO₂ could be enclosed in so-called microbubbles or dissolve in the ice at the time of ice formation and then over a long period of time slowly diffuse into the air bubbles.
- CO₂ in ice samples stored in cold rooms could get lost by diffusion from clathrates or bubbles under high pressure of the surrounding atmosphere.

The likelihood of enrichment of CO₂ in air bubbles by the first two processes is small in Antarctic ice, because records from different ice cores with different impurity concentrations and from drilling sites with different temperatures and accumulation rates provide consistent results. Large scale changes like the industrial increase or the variations of CO₂ concentration within glacial cycles can, therefore, be taken for granted. However, with the improvement of analytical techniques smaller and more detailed variations have been detected. The best test to confirm such variations is the measurement of samples from additional ice cores. This is sometimes difficult, because the synchrony of the age scale of two different ice cores is often not sufficiently precise to allow a comparison of short-term CO₂ variations.

One way of determining whether a single ice core record is reliable or not, is to perform measurements with a high spatial resolution. If CO₂ is measured along a core interval representing only a few years, so that a single sample represents only one

or a fraction of an annual layer, the scatter of the individual results should fall within the analytical uncertainty. Erratic fluctuations along a core section representing a few years cannot represent variations of the atmospheric CO₂ concentration due to the gradual enclosure of air in bubbles. Extensive tests like the ones discussed above show that CO₂ concentration in bubbles can be altered not only in ice from Greenland but also in ice from Antarctica (Stauffer et al., 2003). But while the alterations are large in Greenland ice they are much smaller in Antarctic ice. In general, it can be concluded that the uncertainty is at most 1% or 5 ppm.

While they remain in ice sheets, air trapped in bubbles or clathrates is under high pressure. After recovery of the ice cores the pressure decreases only slowly and the question arises, whether air components could get lost by diffusion from the ice sample to the surrounding atmosphere, if ice is stored for several years in cold rooms. Diffusion of air components, except helium and neon, is so small that it cannot be measured directly. Different estimates give varying results concerning the solubility and diffusion constants for CO₂ and other air components. However, the diffusion of N₂, O₂, and CO₂ is so small that gas losses can be neglected. Indeed it has been shown that for CO₂ no effect can be found due to long-term storage given that a layer of 2–3 mm from the outside of an ice sample is removed prior to analyses (Bereiter et al., 2009).

Background

Snow falling on ice sheets comprises ice crystals that have formed in the cloud, or as clear-air precipitation nucleating on soluble or insoluble particles and capturing further aerosol material on the surfaces of the crystals as they pass through the atmosphere. Particularly in the polar regions (Greenland and Antarctica), and also on cold nonpolar glaciers, there is little surface melting, and the snow builds up, layer upon layer, compacting over time to form ice sheets. In Antarctica, the ice sheet in places exceeds 4000 m in thickness, and may contain ice that is over 1 My old in some places (though not necessarily where the ice is deepest as the insulating character of the ice traps geothermal heat from the bedrock causing the deepest ice to melt). In contrast, the Greenland ice sheet, although reaching over 3000 m, seems to contain continuous layers of ice only as old as around 130 000 years because of melting of the older ice at the base (partly due to the geothermal heat flux, and partly because the surface temperature of central Greenland is higher than that of Antarctica). As these deep ice sheets build up, air percolating around the ice crystals in the upper tens of meters (the firn layer) eventually becomes trapped in bubbles as compaction turns the porous firn into nonporous ice. Thus the ice becomes an archive of precipitation, atmospheric aerosol, and air. This archive can be recovered by drilling into the ice sheets and collecting ice cores, typically around 100 mm in diameter and recovered in lengths of 1–4 m. A profile of past climate and atmospheric change can be constructed by analysis of the isotopic composition of the water molecules, the chemistry of soluble and insoluble particles, and the gases trapped in the air bubbles. Since the early days of ice core research in the 1960s, about two dozen deep ice cores have penetrated through to the base of the ice sheets in Greenland and Antarctica, while considerably more shallow and intermediate depth cores have been recovered spanning the full geographic range of the polar regions as well as from many nonpolar glaciers. The deepest cores may span up to 800 000 years in Antarctica, and to around 130 000 years in Greenland, while shallower cores may only capture the past few decades or centuries.

Many analytical techniques have been brought to bear on ice-core samples, from measuring the concentration and isotopic composition of the trapped gases; the isotopic ratio of the hydrogen and oxygen atoms in the water itself; bulk and trace elements and ions in the meltwater; and the number, size, and elemental composition of the insoluble dust particles. The time resolution of the analyses depends on the depth resolution of the sampling, on the surface accumulation rate (which can be as little as a few centimeters in central Antarctica, to more than 1 m in the coastal regions), and on the layer thickness at depth, which decreases exponentially from the surface to the bed. The potential depth resolution of sampling has

improved over the years as instrumental techniques have improved, and particularly as detection limits of modern analytical instruments have become lower; but there are limits to the time resolution possible due to the mixing of snow during deposition by wind action and by subsequent metamorphism of the snow grains, and due to diffusion of water vapor and some chemical components in the ice. The majority of analytical measurements made on ice cores are essentially destructive – the core needs to be cut into samples and melted for introduction into the instrument or, in the case of air, crushed to release the trapped gases. This, of course, consumes the ice core, and inevitably leads to some compromises between the analytical aims and the availability of ice – particularly in sections of the core that are climatically significant such as transitions between cold and warm periods. There is also a trade-off between the considerable effort required to process and analyze the ice and the resolution (time or depth) desired. A technique that is both nondestructive and requires relatively little effort, yet is potentially capable of high depth resolution, is found in the electrical measurement of ice. Because the electrical logging of cores is usually fast, does not consume ice, offers potentially high depth and time resolution, and responds to both seasonal and climatic changes in the chemistry of the ice, most of the major ice cores drilled in the past three decades have undergone some form of electrical logging. The two main techniques are usually referred to as ‘electrical conductivity measurement’ (ECM) and ‘dielectric profiling’ (DEP).

The electrical properties of ice are dependent on the trapped impurities, as well as on the temperature and density of the ice. The air passages or bubbles in the ice are poor conductors but affect the electrical properties via the density of ice, while the dust particles tend to modify the electrical properties via their effect in neutralizing the acidity of ice rather than conducting significant electrical current. While there were many early studies of the electrical properties of pure laboratory-grown ice (Hobbs, 1974), it was the discovery, by the pioneers of the radar surveys of the ice sheets, that radar-reflecting horizons were visible within the ice sheet which suggested variations in the dielectric properties of natural *in situ* ice (e.g., Paren and Robin, 1975). Hobbs (1974) describes in detail the physics underlying the dielectric dispersion in ice: at low frequencies, typically <100 Hz, the polarization of the water molecule is similar to that of ice, with a relative permittivity of about 90, while at frequencies above several hundred kilohertz, the dipole moment is randomly oriented to the exciting field, the relative permittivity is about 3, and ice has very little absorption. The frequency at which dielectric absorption is greatest is known as the ‘relaxation frequency,’ and is around 12 kHz (Moore and Paren, 1987). Wolff (2000) summarizes the physics of the electrical properties of ice relevant to ice-core measurements, and notes that the properties commonly measured

are the real permittivity and the conductivity (which is itself related to the imaginary permittivity). Above the firn–ice transition, the permittivity is strongly controlled by the density of the ice, while below that depth, chemical impurities, temperature, and the fabric influence the permittivity. For conductivity, the temperature is important, and to some extent the density, but it is the chemical impurities in the ice that have the major influence. To reduce the temperature variability on the permittivity and conductivity, ice cores are normally measured at a temperature of around -20°C , having been stored at a similar and stable temperature for a few days prior to measurement in order to equilibrate the ice. Further, the ice temperature, either at the surface or, more preferably, internally with a temperature probe inserted into a small drilled hole in the core, is measured and a small correction made to the electrical measurements.

DC Conductivity and the ECM Technique

Early work on DC conductivity of ice was often carried out by making low-frequency AC measurements on ice disks in a flat-plate capacitor. This technique is inherently slow, and not appropriate to the continuous electrical logging of long sections of ice. Claus Hammer of the Copenhagen ice-core group made a significant breakthrough in creating a practical technique when he developed a method of continuously measuring the resistance between two electrodes carrying a high DC voltage applied to the surface of ice (Hammer, 1980). This technique became known as the ‘electrical conductivity method,’ commonly referred to as ECM. The technique requires a freshly cut and preferably planed surface, which in some senses implies that the technique is not strictly ‘nondestructive,’ but the common approach is to make the measurement on the first longitudinal cut surface on the core once the initial ice processing begins. A pair of electrodes (often brass) about 10 mm apart is brought into contact with the ice, and a DC voltage of about 1 kV applied across the electrodes. The electrodes are then drawn along the ice at a rate of typically $50\text{--}100\text{ mm s}^{-1}$, and the current flowing (the ECM value typically up to around $50\text{ }\mu\text{A}$) between the electrodes recorded along with the position along the core taken from some form of encoder. Although the ECM is not a direct measurement of the true DC conductivity of ice, there is a close relationship between the two, provided the measurement is carried out on timescales slower than the relaxation frequency but faster than the time for space charges to build up in the ice and reduce the current (Wolff, 2000). Hammer et al. (1980) suggest that this time is of the order of $0.1\text{--}0.5\text{ s}$, with a minimum speed of movement of 20 mm s^{-1} . It is a tribute to the simplicity of the technique and the utility of the ECM data that the Hammer technique is essentially used even today to measure ice-core electrical stratigraphy. Instrument versions might use higher voltages for lower conducting ice, and differing electrode material, size, and spacing, which makes direct quantitative comparison of the magnitude of the ECM signal between cores difficult, but the qualitative shape of the signal in response to ice impurities is remarkably similar. A more recent development has been the multitrack ECM method with a number of electrodes contacting the ice across the width of the core to

construct a two-dimensional image of conductivity, which has been used to determine whether ice layers are dipping or perhaps folded (Taylor and Alley, 2004).

Wolff (2000) summarizes the theory governing DC conductivity in ice, and concludes that in solid ice it can be assumed to be controlled by the displacement of ionic H_3O^+ defects in the lattice. He points out that probably only H^+ , NH_4^+ (or NH_3), and Cl^- (or HCl) are small enough to enter the ice lattice substitutionally and present in sufficient quantities to modify conductivity through the lattice. Larger ions commonly present as impurities in ice, such as NO_3^+ and SO_4^{2-} , may not enter the lattice, and therefore play little role in the conduction mechanism of solid ice. Wolff and Paren (1984) suggested a two-phase model for DC conductivity in natural polar ice, including conduction along liquid acid veins at triple grain boundaries which form a continuous matrix through the ice structure along with solid-phase lattice defect conduction. The later discovery of strong sulfuric acid located at triple grain boundaries in ice (Mulvaney et al., 1988) supports the liquid vein conduction mechanism, particularly because the eutectic temperature of a sulfuric acid/water mixture is well below the coldest polar ice sheet temperature. Indeed, it is commonly observed that the ECM signal recorded in ice (Figure 1) is strongly correlated to the acidity of ice, particularly evident when compared to measurements of the sulfate ion (which may not enter the lattice) which has origins in the seasonal acidic sulfate from the oxidation of marine biogenic sulfurous gases commonly ascribed to dimethyl sulfide and from the sporadic acidic sulfate arising from the oxidation of sulfur dioxide emitted

Figure 1 Short sections of electrical conductivity method (ECM) profiles from two ice cores drilled approximately 160 km apart from (a) the south dome and (b) north dome of Berkner Island, Antarctica, showing clear seasonal cycles. The greater number of peaks in the south dome core indicates a lower accumulation rate than the north dome core (data source: Mulvaney et al., 2002).

Figure 2 The electrodes of the ECM instrument in use in the field on a section of the deep ice core from the NEEM project, Greenland. Photograph by R. Mulvaney.

by volcanoes. But, the observations that the relationship between the measured acidity (measured as H^+) and DC current is not linear (e.g., see Figure 5 in Moore et al., 1992b) and that fluctuations in ECM current persist even in single large crystals in deep ice suggest that solid-phase conduction must also contribute significantly to the measured current flow.

Regardless of the precise physics behind the measured ECM conductivity, the fact that the technique responds well both to local seasonal acidity and to regional or global sporadic acidic events of volcanic origin has proved a remarkable utility for dating ice cores, and it has therefore become a common technique on many ice-core drilling projects. An example of a recent application can be seen in the photograph in Figure 2: the ECM signal is measured using a simple handheld double brass electrode drawn across the planed surfaces of freshly cut lengths of ice cores drilled by the NEEM project in Greenland (<http://neem.dk/>). Since Hammer's (1980) first description of the ECM technique, all the deep ice cores in Greenland drilling projects coordinated by the Copenhagen group have been measured in a similar fashion, allowing dating by counting seasonal layers in the ECM signal (usually alongside parallel seasonal chemical signals measured by a 'continuous flow analysis' technique). Perhaps the best example of multicomponent seasonal layer counting is the establishment of the Greenland GICC05 age scale, which now extends to 60 ka BP (Svensson et al., 2008). The appearance of sporadic larger peaks in ECM conductivity of volcanic origin allows for checks on the seasonal dating where the date of the volcanic eruption is known, and additionally allows for cross-correlation of the dating between cores by matching the pattern of the large conductivity peaks (e.g., Taylor et al., 1993).

Dielectric Profiling

While the DC conductivity of pure ice appears to be related to H_3O^+ defects in the lattice and conduction through the grain boundary and vein network, Moore et al. (1992b) attributes the high-frequency AC dielectric conductivity to movements of Bjerrum L- and D-defects in the ice, and associates these by experimental observation to the H^+ , NH_4^+ , and Cl^- ions (most other major ions such as NO_3^+ and SO_4^{2-} are too large to enter

the lattice and to contribute to the dielectric conductance). As with the ECM technique, the early AC dielectric properties of ice were traditionally measured on disks of ice sandwiched between two guarded parallel plates. The first practical system for routinely measuring the DEP of ice and relating the data to the bulk chemistry of the core was described by Moore and Paren (1987) and Moore et al. (1989), who demonstrated a method that was not only nondestructive but also did not require either a fresh surface or contact between the electrodes and the ice, implying a polythene sleeve could be left on the ice to reduce contamination. In Moore's instrument, the ice acts as a capacitor between two curved aluminum electrodes, each subtending an arc of 108° and at least as long as the ice core to be measured. The lower electrode was continuous along the core, and connected to the high-voltage side of a measuring device (an LCR meter measuring inductance L , conductance C , and resistance R at a range of frequencies from hertz to megahertz). The upper electrode consisted of a number of similarly curved but separated electrodes each of 50 mm length along the core, while two earthed flat-plate aluminum side guard electrodes ran the whole length of the electrode assembly to confine the field to be close to parallel across the core. No electrical contact between the electrodes and the ice was required for the technique, which was achieved by anodizing the aluminum and keeping a plastic sleeve around the ice and a small air gap with the upper electrodes. The whole electrode assembly was then housed in an aluminum case to isolate it from electromagnetic interference. A switching device connected each of the narrow upper electrodes in turn to the low-voltage side of the measuring device, and the sequence of capacitance and conductance measurements was made at a range of frequencies from 20 Hz to 300 kHz along a 1-m length of core in 30 min. A development model of this device was used successfully on the 3029-m deep Greenland Ice Core Project (GRIP) and on the 3270-m deep ice core drilled by the EPICA project at Dome C. In this instrument (Figure 3), 120 electrodes of 20 mm width were arranged along the length of the instrument, and a switching device connected each electrode in turn to the measuring device, giving an effective depth resolution of 20 mm. This instrument produced a DEP record from the full core, demonstrating the glacial-interglacial contrast in electrical properties of the ice clearly (Figure 4). Improvements to the early instrumentation followed from a better understanding of the geometry of the electrodes (Wilhelms et al., 1998). Most modern DEP instruments use a single, narrow (a few millimeters) central electrode with earthed guard electrodes either side, which is moved by a stepper motor along the length of a core which sits on a continuous lower electrode (e.g., see Figure 2 in Hofstede et al., 2004), while an LCR measuring device records the conductance and impedance at frequencies up to 1 MHz. As noted earlier, temperature has an effect on all electrical measurements, which is therefore controlled by buffering the ice in the field or laboratory to achieve a uniform temperature throughout the core section, and the results corrected for the actual temperature measured of the ice. The spatial resolution of the DEP tends to be limited to about 10–20 mm but, in a further development of the DEP, Fujita et al. (2002) uses a hybrid technique applying a high-frequency current to a pair of electrodes dragged across the surface of the core, which is claimed to give a resolution more similar to that of the ECM.

Figure 3 A section of 2.2 m of EPICA Dome C ice core loaded onto the DEP instrument in the field in Antarctica: the ice core is marked up into 55 cm 'bags' during the processing, and here bags 173–176 (94.6–96.8 m) are being made ready for measurement. Photograph by R. Mulvaney.

Figure 4 The EPICA Dome C stable water isotope and electrical data: (a) deuterium data showing eight glacial–interglacial climate cycles; (b) ECM conductivity; (c) 100-kHz DEP conductance (data source: [EPICA Community Members, 2004](#); [Stauffer et al., 2004](#)).

The DEP responds strongly to acidity, but has also been shown to respond more weakly to sea salt ions, particularly Cl^- ([Moore et al., 1992a](#)) and NH_4^+ ([Moore et al., 1994](#)) which are probably dispersed within the fabric of the ice. In contrast to its DC conductivity, pure ice has a significant high frequency conductivity, which can be seen as a background response even when concentrations of impurities are low. There is a significant dependence on the density of the ice (effectively the quantity of ice between the electrodes and the dielectric capacitance of air trapped between ice grains), and this is clearly seen in the DEP response from the upper 100 m of ice-core records (e.g., [Barnes et al., 2002](#)), which follows the densification curve of the ice ([Figure 5](#)). [Wolff et al. \(1995\)](#)

demonstrate the dependence of the DEP signal on the concentrations of acidity, ammonium, and chloride in the ice over a complete glacial to interglacial climate cycle in a Greenland core, and note that there is no evidence for any changes in the DEP (and ECM) electrical response to the depth or age of the ice, other than via the changes in chemistry.

Uses of Electrical Measurements

Because of their nondestructive nature, electrical measurements tend to be applied early in the analysis of many ice cores. They are often made in the field at the drilling site,

Figure 5 Comparison of (a) the DEP 50-kHz conductance (blue curve) with (b) the nonsea-salt sulfate impurities (black curve) in a core from Dronning Maud Land, Antarctica. The nonsea-salt sulfate is calculated from the total sulfate measured in the ice minus the contribution from sea salt calculated from a conservative sea-salt marker such as sodium, and is the sulfate arising from oxidation of marine biogenic and volcanic gases. The slope on the DEP signal is due to the densification of firn to ice.

offering an early indication of the stratigraphy of the ice through the recognition of seasonal layers and well-dated volcanic horizons in cores from high accumulation sites to patterns of volcanic horizons and the contrast between glacial and interglacial ice in the deep cores from low accumulation sites. The DEP response increases with the volume of ice between the electrodes, so it is commonly the first measurement technique carried out on the ice and can even be applied while the ice remains in the polythene sleeve used to protect the ice during transport to the laboratory. Most of the major deep ice-core drilling projects have made these measurements in the field shortly after drilling the ice (after allowing the ice to reach a thermal equilibrium, generally at a temperature of around -20°). In these projects, the ECM is then usually carried out on the first lengthways-cut surface of the ice, though a planed surface on the outer edge of the core is normally effective too.

For shallow and intermediate depth cores taken from relatively high accumulation sites, and particularly in near-coastal regions, the ECM signal often shows a clear seasonal cycle which can be used to date the core by counting annual layers (Figure 1). This layer counting technique has reached a pinnacle of achievement in the dating of many of the Greenland ice cores which, in contrast to the deep Antarctic cores, are commonly recovered in areas of sufficiently high accumulation for the seasonal cycles in acidity and, therefore, the ECM response to be retained even at great depth. Thus the ECM signal and continuous chemical analysis defining seasonal layers in other impurities have been used together to date the cores with some degree of reliability to as much as 60 ka (e.g., Svensson et al., 2008). Even where seasonal layers in the ECM are not resolved, the pattern of discrete peaks resulting from volcanic deposition of acidity can be used to cross-correlate between ice cores from different sites. Clausen et al. (1997) compares 4000 years of volcanic horizons between the Greenland GRIP and Dye 3 cores. Vinther et al. (2008) synchronizes several Canadian high Arctic cores with the Renland, GRIP, and NGRIP cores from Greenland. Taylor et al. (1993) shows a particularly

convincing match in the pattern of ECM peaks in two separate 10-m sections taken from depths of more than 2300 m in the Greenland Ice Sheet Project 2 (GISP2) and GRIP cores. Taylor et al. (1993, 1997) goes on further to demonstrate that the ECM signal changes by a factor of 40 between stadial and interstadial periods, with the strongest ECM response in the warm periods, and a low signal from the cold periods where a high concentration of alkaline dust tends to neutralize the acidity of the ice suppressing the ECM response. This pattern of high and low ECM signals is easily matched between the two cores and, taken together with the recognizable patterns in the volcanic peaks, the ECM profiles form a powerful method of tying the age of the ice between cores. Few of the very deepest (>3000 m) cores from Antarctica have sufficient accumulation at the surface to avoid mixing of the snow by surface drifting, effectively eliminating the seasonal signal in impurities. However, for the first of the deep Antarctic ice cores from Byrd Station, where the present-day accumulation is around half that of central Greenland, the seasonal signal appear to be preserved. Hammer et al. (1994) were still able to readily identify some seasonal cycles in the Byrd core ECM to a depth of 1750 m, or 40 000 years, and could pick out some layers even deeper than this. While not able to count seasonal cycles continuously from the surface, the layer thickness at various depths does contribute significantly to the age–depth model. At Siple Dome, Antarctica, Taylor et al. (2004) included an ECM record in their seasonal layer counting across the full Holocene period.

In central Antarctica, away from the coastal region with its particularly strong seasonal acidic signal from seasonal biogenic sources and marine sea salt input to the ice, the DEP profiles from ice cores have proven particularly useful in picking out the acidity from volcanic events. Over the most recent 1000 years, many of these volcanic eruptions are historically recorded events and therefore well dated, and can be used as reference horizons to date cores. Karlof et al. (2000) in fact have demonstrated that the contrast between the volcanic peaks and the background seasonal signal is greater in the

DEP than in the ECM, making DEP probably the more useful technique, at least in regions closer to the coast. In a DEP record from a 100-m core from the Mizuho Plateau in Dronning Maud Land, Moore et al. (1991) picked out horizons attributed to the eruptions of Agung (1963), Krakatau (1873), Tambora (1815), and the eruptions of 1601 and 1259. These horizons can be picked out in the majority of DEP profiles from Antarctic ice cores, and, indeed, the sequence of four volcanic peaks around the year 1259 is quite distinctive (Figure 5). Hofstede et al. (2004) used DEP profiles from six shallow cores (up to 150 m, but all spanning at least 1000 years) from Dronning Maud Land to identify the principal volcanic peaks, and then derived the mean accumulation rate experienced at each site between successive horizons to determine the spatial and temporal pattern of accumulation in this region over the past millennium. Udisti et al. (2000) used ECM, DEP, and chemistry from continuous flow instruments to pick out volcanic horizons, contributing to the dating of the Holocene section of the Dome C deep ice core.

Electrical Properties of the Ice Sheet

The discovery of internal reflecting horizons in the early radar sounding of ice sheets suggested a wide variation in the dielectric properties of natural ice (e.g., Paren and Robin, 1975), which eventually led to the continuous electrical measurement techniques on ice cores. Radar layers originate from contrast in the real and imaginary permittivity of ice layers, and they arise ultimately from contrasts in the density, fabric, and chemistry of the ice. Now that the electrical profiles of deep ice cores are routinely measured, interest in modeling the radar response of the ice column has increased. Hempel et al. (2000) compared the radar-reflecting horizons in the Greenland ice sheet with the ECM trace from the GRIP core. After accounting for the density profile, and correcting for the wave velocity of radar in ice, they concluded that the acidic layers of volcanic origin show up as radar horizons. Indeed, it has been clear for a long time that there is a clear contrast between the numerous radar returns from the acidic Holocene ice and the paucity of returns from the dust-laden glacial ice where the acidity is neutralized, punctuated with strong reflectors thought to originate from the acidic interstadial layers. Using the DEP record from the same GRIP core, Miners et al. (2002) constructed a synthetic radargram that managed to pick out many of the larger reflecting horizons below 500 m (where, presumably, radar returns from density contrasts are less significant than chemical contrasts in the ice), and nearly all the features below 1500 m, including some of the interstadial events in the glacial ice. In Antarctica, Eisen et al. (2003) have deconvoluted DEP records from a 150-m core to produce a synthetic radargram to compare with high-frequency shallow radar profiles and shown that only some reflections in the upper layers of the firn correlate to acidic horizons. The use of DEP profiles from the deeper Antarctic ice cores offers a refinement of the synthetic radargram method, which has application in dating and tracing isochronal layers in radar profiles between ice-core sites across the ice sheet (Eisen et al., 2006).

Introduction

Ice cores recovered from polar and high-elevation regions provide a unique and valuable archive of past atmospheric conditions, in large part because of the numerous physical and chemical measurements that can be performed at any given depth, and because the transformation of snow to firn to ice on a glacier or ice sheet provides two basic sets of atmospheric information. First, when firn turns into ice, bubbles are formed that trap ambient air whose composition provides information on atmospheric trace gases (e.g., CO₂, CH₄) at the time of ice formation. Second, aerosols and water-soluble gas species can be trapped during precipitation, as well as deposited directly on the snow surface. While the term ‘glaciochemistry’ is broad and could conceivably encompass all chemical measurements made on ice core samples, in practice, it generally represents the soluble mineral and organic components originally deposited on the snow surface (Legrand and Mayewski, 1997). Measurement of the suite of major ions (Na⁺, Mg²⁺, Ca²⁺, K⁺, NH₄⁺, Cl[−], NO₃[−], and SO₄^{2−}) represents approximately 95% of the soluble composition of the atmosphere, and therefore, provides a powerful tool for investigating modern and past changes in atmospheric chemistry. Ions from soluble organic acids, such as formate (HCOO[−]), acetate (CH₃COO[−]), and oxylate (C₂O₄[−]), methylsulfonate (CH₃SO₃[−]; MS[−]), and other volatile species such as hydrogen peroxide (H₂O₂) and formaldehyde (HCHO) have been measured at various ice core sites and used to study atmospheric and biogeochemical processes. However, the major ion suite is most commonly measured in ice cores, and there is an extensive dataset available from a globally distributed set of ice core sites. Because of the varied geographic positions (e.g., elevation, distance from ocean or arid regions, etc.) of these sites, major ion (plus MS[−]) concentrations in ice cores show a wide range of values based on temporal changes in chemical source strength, climate dynamics, and biogeochemical processes. This article therefore contains a review of current issues in the field of ice core glaciochemistry (restricted here to major ions plus MS[−]), and summarizes information related to chemical sources, transport, deposition, and interpretation in terms of paleoclimate and paleoenvironmental change. For a more thorough understanding of the range of chemical species studied in ice cores, see elsewhere in this encyclopedia.

Glaciochemical Background and Measurement

The composition of precipitation in polar and alpine regions contains various soluble impurities, introduced to the atmosphere either directly as primary aerosols (e.g., dust entrained from terrestrial surfaces), or produced within the atmosphere (secondary aerosols) during the oxidation of trace gases

involved in the sulfur, nitrogen, halogen, or carbon cycles. Some soluble ion species have multiple sources (Legrand and Mayewski, 1997); for example, SO₄^{2−} can be linked to both primary aerosols (sea salt and dust) as well as secondary aerosols (from the oxidation of sulfur gases produced by volcanic activity, anthropogenic [human] activities, and the biosphere). It is therefore necessary to study all soluble species present in ice core samples in order to understand and reconstruct the original association of the ions. The ionic budget (Σ ; sum of all ion species present) in polar and alpine snow can generally be written as follows (concentrations in microequivalents per liter, $\mu\text{eq L}^{-1}$):

$$\begin{aligned} \Sigma = & [\text{Na}^+] + [\text{NH}_4^+] + [\text{K}^+] + [\text{H}^+] + [\text{Ca}^{2+}] + [\text{Mg}^{2+}] \\ & + [\text{F}^-] + [\text{Cl}^-] + [\text{NO}_3^-] + [\text{SO}_4^{2-}] + [\text{CH}_3\text{SO}_3^-] \\ & + [\text{HCOO}^-] + [\text{CH}_3\text{COO}^-] \end{aligned}$$

In most situations, the concentrations of F[−] and the light carboxylates are insignificant. While measurements of MS[−] are important in the study of the atmospheric sulfur cycle, concentrations of the compound are usually low. Therefore, ΔC , the imbalance between cations and anions, can usually be simplified to:

$$\begin{aligned} \Delta C = & [\text{Na}^+] + [\text{NH}_4^+] + [\text{K}^+] + [\text{H}^+] + [\text{Ca}^{2+}] + [\text{Mg}^{2+}] \\ & - [\text{Cl}^-] + [\text{NO}_3^-] + [\text{SO}_4^{2-}] \end{aligned}$$

Likewise, the balance achieved between cations and anions ($\Delta C=0$), a useful measure for evaluating original chemical deposition forms, can be calculated as:

$$\begin{aligned} & [\text{Na}^+] + [\text{NH}_4^+] + [\text{K}^+] + [\text{H}^+] + [\text{Ca}^{2+}] + [\text{Mg}^{2+}] \\ & = [\text{Cl}^-] + [\text{NO}_3^-] + [\text{SO}_4^{2-}] \end{aligned}$$

Deposition of primary and secondary aerosols to the glacier or ice sheet surface occurs via several mechanisms, and therefore using soluble ion data to reconstruct past atmospheric chemical concentrations requires some knowledge of these processes. In the case of wet deposition, the aerosol falls within or is attached to a snowflake after either serving as a condensation nucleus or being scavenged by the falling snowflake. During dry deposition, the air-to-surface transfer occurs without any associated water transfer. To account for these processes when using ice core glaciochemical data, two procedures are common: (1) ice core time series of ion concentrations (e.g., parts per billion [ppb] or $\mu\text{eq L}^{-1}$) are interpreted directly, and (2) the estimated chemical flux (e.g., $\text{ng cm}^{-2} \text{ year}^{-1}$) is calculated and interpreted. Chemical fluxes are calculated by multiplying the sample concentration by the estimated H₂O flux (accumulation). In some cases, a qualitative examination of either concentration or flux time series yields similar results. For example, the deposition of Ca²⁺ on the Antarctic polar plateau and coastal sites was clearly higher during the Last Glacial Maximum (LGM) when either ice core

Figure 1 Nonsea salt (nss) Ca^{2+} concentrations (black) from the Taylor Dome, Antarctica ice core (Mayewski et al., 1996), and 50-year average nssCa^{2+} flux values (red) from the EPICA Dome C (EDC), Antarctica ice core (Rothlisberger et al., 2002).

Figure 2 nssCa^{2+} fluxes from the EPICA Dome C (Fischer et al., 2007) and EPICA Dronning Maud Land (EDML; Fischer et al., 2007) ice cores, and nssCa^{2+} concentrations from the Siple Dome ice core, West Antarctica (Mayewski et al., 2009).

concentration or flux estimates are viewed (Figures 1 and 2). However, detailed quantitative analyses often require a more rigorous knowledge of site-specific air-snow-surface transfer functions, and justification for using either concentration or flux time series is necessary (e.g., Meeker et al., 1997). In addition, any postdepositional modification of the original chemical signal needs to be taken into account when reconstructing past atmospheric concentrations (e.g., Barnes et al., 2003).

Glaciochemical measurement techniques have evolved over the past ~30 years; however, the majority of soluble ion data have been and continue to be produced by ion chromatography (IC; e.g., Buck et al., 1992; Curran and Palmer, 2001; Legrand et al., 1984). Advances in IC technology have allowed much lower concentration measurements to be made with high precision, such that data produced from the most remote and pristine polar and alpine locations are now reasonably

routine. Analytical challenges still occur in certain situations, such as with samples collected from arid regions that have very high ion concentrations and particulate material that impede IC column performance. Decontamination of recovered ice cores is crucial to producing reliable glaciochemical data, and is as important as the chemical measurement itself. Early methods (still frequently used at high-accumulation sites) involved removing the outer portion of the core by rinsing with ultra-pure water, or by the physical removal of the outer core by scraping. More recently, several international groups have developed continuous melting systems that utilize a heated melting head that produces samples from the inner and outer portions of the core, thereby avoiding contamination from the outer core and providing the opportunity for high-resolution (small depth interval) measurements. Samples are either collected discretely (e.g., the melt water stream is collected into

individual sample vials at a specified interval; Osterberg et al., 2006), or injected directly into an instrument during continuous flow analysis (CFA; e.g., Fuhrer et al., 1993; Kaufmann et al., 2008; Rothlisberger et al., 2000; Sigg et al., 1994). When samples are collected discretely, standard IC techniques are used to analyze a full suite of ion species. In CFA, reagents are added to the sample stream, and measurement is typically via fluorometric (Na^+ , NH_4^+ , Ca^{2+}) or absorption (Na^+ , NO_3^-) techniques. A third analytical method has recently been developed known as fast ion chromatography (FIC), and is designed specifically for high-resolution ice core measurements, where a portion of the steady sample stream is injected into an IC at a specified time interval (Cole-Dai et al., 2006; Traversi et al., 2009; Wolff et al., 2006). FIC and CFA techniques currently have limitations in terms of the number of ion species that can be analyzed; however, as techniques evolve, other species will likely be added. Good agreement is found when ion concentrations measured on the same samples with the three different methods are compared (Littot et al., 2002). Soluble ion concentrations are typically reported in either mass-by-mass units (e.g., ppb), or molar units ($\mu\text{mol L}^{-1}$ or $\mu\text{eq L}^{-1}$).

Glaciochemical Sources and Spatial/Temporal Variability

The sources of soluble ion species in polar and alpine ice cores can be grouped into several general categories based on the original aerosol formation process. Because several ion species have multiple sources, statistical techniques are often applied to differentiate compounds responsible for ion deposition. In particular, multivariate techniques have been developed to deal with multiple chemical sources in a more quantitative fashion, in addition to accounting for factors inherent in ice core glaciochemical studies such as nonuniform sampling, nonstationary processes, and sporadic events (Meeker et al., 1995; Peixoto and Oort, 1992).

Sea Salt Aerosol

Sea salt aerosols are one of the major sources of impurities in polar ice cores, and contribute a significant portion of several species (notably Na^+ , Cl^- , SO_4^{2-} , and Mg^{2+}) to the ion balance. Originally, the source of the sea salt aerosol reaching coastal and inland plateau sites was thought to be primarily bubbles bursting over open ocean water. Because ion species associated with sea salt typically peak during winter, and also show elevated concentrations during glacial periods, the role of sea ice was not clear. Increased sea ice extent during winter and glacial periods should presumably lead to a decrease in the amount of sea salt aerosol reaching a particular site. One possibility for explaining this discrepancy is that increased storminess over the ocean and enhanced transport of sea salt aerosols inland during winter and glacial periods more than offsets the greater distance (Petit et al., 1999). Another possibility is that sea salt aerosol (particularly ssNa) is produced from newly formed sea ice, where highly saline brine and fragile frost flowers form a very effective source of aerosol in the winter (Wolff et al., 2003). A sea ice source is supported by the chemical signature of sea salt aerosols (e.g., depletion of SO_4^{2-}) during winter (e.g., Rothlisberger et al., 2010). Both of these factors (atmospheric dynamics and sea ice) likely contribute to sea salt deposition at a particular polar site, with each process being relatively more important on different timescales. Correlation of annually dated sea salt time series in Antarctica (Kreutz et al., 2000) and Greenland (Meeker and Mayewski, 2002) with sea level pressure records suggests a strong transport influence at these sites and timescales, while an ice core sea salt record from the Penny Ice Cap, Baffin Island is significantly correlated with local sea ice extent (Grumet et al., 2001). On glacial–interglacial timescales, sea salt records from Greenland (Figure 3; Mayewski et al., 1997) and Antarctica (Rothlisberger et al., 2002; Wolff et al., 2010) display significant concentration increases during glacial periods, suggesting the influence of both enhanced atmospheric transport

Figure 3 Sea salt (ss) Na^+ concentrations and nssCa^{2+} concentrations from the GISP2 ice core (Mayewski et al., 1997). Both datasets are 50-year averages.

and sea ice extent. At peak glacial conditions, however, ice core sea salt records may not be sensitive to sea ice variability; thus, incorporation of marine sediment core data can be useful (Rothlisberger et al., 2010). For high-elevation sites in mid- and low-latitude regions, the contribution of sea salt aerosol varies greatly depending on location relative to an ocean source. In Asia, most ice coring sites are located far from a marine source, and therefore, sea salt contributes little to the overall ion budget (Kang et al., 2004). In coastal ranges (e.g., St. Elias Mountains in Alaska/Yukon) or sites relatively close to the ocean (e.g., the Andes), the relative contribution of sea salt aerosol depends on elevation and accumulation rate (Thompson et al., 1998; Yalcin et al., 2006).

The calculation of the percentage of sea salt in any particular sample is an important step in determining the relative contribution to various species. The simplest calculation is based on the assumption that one ion species is derived solely from sea salt, and therefore standard seawater ion ratios can be used to calculate the sea salt (ss) and nonsea salt (nss) contribution for other species. In Antarctica, Na^+ is generally thought to have no other significant source, and after deposition behaves conservatively. In this case, calculation of nssCa^{2+} , for example, would be:

$$[\text{nssCa}^{2+} = \text{Ca}^{2+}] - [\text{Na}^+] \times [R_m]$$

where R_m is the $\text{Ca}^{2+}/\text{Na}^+$ ratio (0.038) found in marine aerosols. A slightly more sophisticated approach is to recognize that some Na^+ derives from other sources, and therefore, solve two equations simultaneously:

$$[\text{ssNa}^+] = [\text{Na}^+] - \frac{[\text{nssCa}^{2+}]}{R_c}$$

$$[\text{nssCa}^{2+}] = [\text{Ca}^{2+}] - [\text{ssNa}^+] \times R_m$$

where R_c is the $\text{Ca}^{2+}/\text{Na}^+$ ratio (1.78) found in average crust. Finally, models that estimate ss and nss components by an iterative process in which each sample is tested to determine which species is the most conservative (limiting) are useful for time-series calculations where the relative importance of sea salt aerosols may change (O'Brien et al., 1995). All of these methods assume that fractionation of sea salt aerosols during transport via reaction with acids, and possible loss after deposition, does not occur (Rothlisberger et al., 2003).

Terrestrial Dust

Dust records from polar and alpine ice cores have been widely used to infer past changes in atmospheric circulation and climatic/environmental conditions in dust source regions. Dust is important in the climate system because of its scattering effect on incoming solar radiation, and dust particles also serve as cloud condensation nuclei. Dust is also an important source of the trace nutrient iron (Fe) to the world's oceans, where it can have a fertilizing effect on primary production and nitrogen fixation (e.g., Martin et al., 1990; Moore et al., 2009). Thus, ice core measurements of dust allow us to estimate the magnitude of these effects through time. Measurement of dust (mineral aerosols) in polar ice cores can be accomplished in several ways, including both direct and proxy measurements. The most commonly used dust proxy is nssCa^{2+} , as the major portion of

nssCa^{2+} detected in ice cores comes from continental dust (Legrand and Mayewski, 1997) and it can be measured in a straightforward manner using IC. While it has been shown to record major changes in dust deposition on glacial–interglacial timescales (Figures 1–3) nssCa^{2+} varies in its reproducibility of insoluble particle measurements by up to a factor of 2 between low (interglacial) and high (glacial) dust concentrations (Ruth et al., 2008). This may indicate variable dust composition, and in fact, work in East Antarctica has found evidence of calcium carbonates at coastal sites (Sala et al., 2008). Ruth et al. (2008) suggest that quantitative reconstruction of dust deposition depends on the analysis method used.

In addition to nssCa^{2+} , the nss fractions of several other species (including Mg^{2+} , Na^+ , K^+ , SO_4^{2-} , NO_3^- , Cl^-) can be linked to insoluble silicate or soluble carbonate or evaporite (e.g., gypsum, halite) minerals derived from terrestrial sites. Snow samples and ice cores collected from sites located close to arid regions therefore have a correspondingly high dust load. High-elevation sites in Asia, either on or near the Tibetan Plateau, show elevated concentrations of all measured ions related to dust input (Thompson et al., 1997), as do European alpine sites influenced by Saharan dust (Schwikowski et al., 1999). Likewise, South American sites near the dry Altiplano region have enhanced ion concentrations during periods of lake desiccation (Thompson et al., 1998). In modern polar snow, the terrestrial dust contribution is usually small due to the large distance from available sources (Legrand and Mayewski, 1997), and in general dust only contributes a measurable nss fraction to Ca^{2+} and potentially Mg^{2+} and K^+ . Exceptions exist in ice-free regions such as the Dry Valleys, Antarctica, where exposed soils provide a source of soluble particulate material (Williamson et al., 2007). During the Holocene, changes in dust transport to Greenland are reflected in ice core nssCa^{2+} , nssMg^{2+} , and nssK^+ concentrations (O'Brien et al., 1995), and correlation with instrumental data as well as trace element isotopic work indicates that an Asian source is most probable (Bory et al., 2003; Meeker and Mayewski, 2002).

During the LGM, nssCa^{2+} concentrations show dramatic increases on the Antarctic (Figures 1 and 2) and Greenland (Figure 3) polar plateaus, as well as significant millennial-scale variability (Mayewski et al., 1996, 1997; Petit et al., 1999; Rothlisberger et al., 2002). In general, atmospheric dust loadings globally were a factor of 2–4 higher during glacial periods than during interglacials, with the northern hemisphere producing the majority of dust on a global scale (Fischer et al., 2007; Kohfeld and Harrison, 2002; Lambert et al., 2008; Maher et al., 2010). Modeling studies have suggested that changes in LGM climate (increased surface wind speed, reduced atmospheric and soil moisture, higher aerosol transport efficiency) and vegetation were largely responsible for the observed increases in dust deposition (e.g., Mahowald et al., 2006), while glacial activity may have been an important local factor (Sugden et al., 2009). However, a synthesis of empirical and modeling results that tests these various factors points to wind gustiness as a primary first-order driver of dust emissions during the LGM (McGee et al., 2010).

Volcanic Aerosols

Volcanic eruptions emit large amounts of particulate matter and gases (mainly SO_2) to different heights in the atmosphere

depending on eruption intensity and magma composition. Sulfate aerosols formed from the atmospheric oxidation of SO_2 and gas-to-particle conversions can be transported on regional to global scales, particularly when injected into the stratosphere (upper atmosphere), and are deposited on alpine glaciers and polar ice sheets. Sulfate ice core stratigraphy can be used to interpret the impact of individual eruptions on the atmospheric aerosol load, and any associated climate impacts. In addition to SO_4^{2-} , volcanic aerosols can also contribute other species to the overall ionic budget, including Cl^- and F^- (Herron, 1982). In the Northern Hemisphere, several ice core locations record both global and local/regional scale eruptions, particularly from the Icelandic and North Pacific regions (Zielinski et al., 1994). In the Southern Hemisphere, ice core records from coastal (Talos Dome) and West Antarctic sites (Kurbatov et al., 2006; Langway et al., 1995) also show a mixture of global and local/regional eruptions. In contrast, East Antarctic plateau ice cores generally are removed from any local-scale volcanic signals and therefore provide complementary estimates of explosive global-scale eruptions for use in bipolar comparisons (Cole-Dai et al., 2000). Several methods are used to estimate the contribution of volcanic nssSO_4^{2-} to the total SO_4^{2-} deposition, including smoothing and residual analysis, multivariate statistics, and definitions based on signals above a standard deviation cutoff. Isotopic analysis of sulfate can be used to differentiate among sources; for example, in West Antarctica, volcanic and stratospheric sources of sulfate dominate, while marine sources are more important in East Antarctica (e.g., Kunasek et al., 2010; Pruetz et al., 2004). Ice core-based reconstructions of past volcanic eruption frequency and intensity have, for example, identified an increase in volcanic activity in the early Holocene (Zielinski et al., 1994; Figure 4), possibly related to climatic cooling, and in the late Holocene (Castellano et al., 2005). In addition, ice core volcanic eruption histories are often used in climate forcing estimates input to climate models.

Biogenic Emissions

Biogenic emissions play a large role in the atmospheric sulfur cycle. In the remote unpolluted marine atmosphere, oxidation of dimethylsulfide (DMS) released from marine organisms represents a major source of nssSO_4^{2-} , both on local and global scales. In addition, the oxidation of DMS also produces methanesulfonic acid (measured as methylsulfonate; MS^-), and this formation pathway is the only known source of MS^- . Therefore, the measurement of both nssSO_4^{2-} and MS^- in ice cores represents a potential tool for deconvolving marine biogenic from nonbiogenic sulfur sources, and potentially for reconstruction of past changes in DMS emissions and hence ocean productivity (Legrand, 1995). Given that MS^- and nssSO_4^{2-} both exist as submicron aerosols, and therefore should have similar atmospheric transport and deposition processes, the ratio of $\text{MS}^-/\text{nssSO}_4^{2-}$ (R) in ice cores may provide a tool for estimating marine emissions. Such measurements are particularly relevant in Antarctica, given the surrounding open and ice-covered ocean regions, and to a somewhat lesser extent in Northern Hemisphere sites that are located near coastal regions. Recent sulfur aerosol and surface snow studies and modeling results have shown that R values vary spatially in Antarctica; seasonal values vary based on transport and chemical source region, and inland Antarctic ice cores sites and R values may provide large-scale estimates of bioproductivity. Therefore, with careful study of Antarctic snow and ice cores, R values may lead to an improved understanding of the oxidative capacity of the atmosphere, the temperature of the atmospheric oxidation of DMS, and the aging of marine air masses during their transport from source regions to Antarctica. Because the oxidation of DMS is the only known source of MS^- , several authors have used ice core MS^- concentrations to investigate past variability in the sulfur cycle, particularly the relationships among productivity, climate, and sea ice. MS^- concentrations from the Vostok ice core (Legrand et al.,

Figure 4 Volcanic SO_4^{2-} concentrations from the GISP2 ice core (Zielinski et al., 1994). The volcanic fraction of total SO_4^{2-} concentration are residuals calculated using a low-tension robust spline method.

1991) display an increase during the LGM, suggesting enhanced ocean productivity during periods of colder temperatures and decreased greenhouse gas concentrations. On shorter (interannual) timescales, correlations between South Pole ice core MS^- concentrations and the El Niño–Southern Oscillation have been found (Meyerson et al., 2002), indicating a link between low and high-latitude ocean/atmosphere circulation and marine productivity. Finally, several authors have found correlations between snow and ice core MS^- concentrations and sea ice extent (Abram et al., 2007; Curran et al., 2003; Rhodes et al., 2009), suggesting that algal productivity within and on top of sea ice may contribute to atmospheric DMS and hence influence ice core MS^- values.

Ice core NH_4^+ concentrations primarily arise from biological emissions of ammonia from plants, soils, and animals, bacterial decomposition, burning of biological materials (forest and grass fires), and potentially marine biological emissions. In the high-latitude Northern Hemisphere, NH_4^+ is present in significant amounts in precipitation, and ice core time series have been useful for reconstructing the history of forest fires from the boreal zone (Savarino and Legrand, 1998). On longer (multidecadal to glacial–interglacial) timescales, NH_4^+ concentrations in Greenland are mainly related to continental biogenic emissions from soils, and no evidence has been found for a significant marine contribution. A study of NH_4^+ concentrations in the Greenland Ice Sheet Project 2 (GISP2) core (Meeker et al., 1997) found that orbital parameters (summer forcing associated with the precessional cycle) and ice volume exerted a strong control on continental biogenic emissions over the past 110 000 years (Figure 5). In Antarctica, NH_4^+ concentrations in coastal aerosol and snow are highly variable and likely related to ornithogenic (penguin) soils, while oceanic emissions appear to play a minor role. Therefore, the low concentrations of NH_4^+ from inland sites remain

difficult both to measure and to interpret. In alpine regions, industrial and agricultural emissions likely impact snow and ice core NH_4^+ concentrations.

Nitrogen Cycling

To study past changes in atmospheric NO_x (NO and NO_2) concentration, nitrate (NO_3^-), an oxidation product of NO_x , has often been measured in polar ice cores (e.g., Wolff, 1995). Some features in the NO_3^- records can be readily explained, such as the clear increase since 1940 in Greenland ice cores attributed to NO_x emissions from industrialized countries (Mayewski et al., 1986). However, the interpretation of NO_3^- records beyond the anthropogenic era in Greenland, and in Antarctica in general, remains difficult. Several minor sources of NO_x have been suggested, including meteorite impact, supernovae, and solar modulation (sunspot cycle, solar proton events). The main sources are considered to be NO_x production in the stratosphere and troposphere by lightning. Recent studies of atmospheric NO_y (NO_x , HNO_3 , N_2O_5 , particulate and organic nitrates) have shown considerable amounts of organic nitrate, further complicating the interpretation of ice core NO_3^- time-series records. Studies have demonstrated that depositional and postdepositional processes have a strong influence on NO_3^- concentrations preserved in snow and ice cores (Wolff, 1995; Wolff et al., 2010 and references therein). In particular, it appears that changes in climate (temperature and accumulation rate) and atmospheric chemistry (Ca^{2+} concentrations) had a strong impact on the preservation of NO_3^- during the Holocene and LGM in the polar regions. At sites where potential NO_3^- sources may be close, changes in forest cover and local terrestrial biogeochemistry may explain glacial–interglacial NO_3^- concentration changes (Thompson et al., 1998).

Figure 5 Ammonium (NH_4^+) concentration from the GISP2 ice core (Meeker et al., 1997). The green line is 50-year averaged data, and the black line is a low-tension robust spline chosen to highlight millennial-scale variability.

Figure 6 Sulfate (SO_4^{2-} ; blue) and nitrate (NO_3^- ; green) concentrations from the GISP2 ice core (Mayewski et al., 1986, 1990), showing a clear increase in the twentieth century due to anthropogenic emissions.

Anthropogenic Emissions

Emissions of SO_2 and NO_x from industrial processes and fossil fuel use have been a source for SO_4^{2-} and NO_3^- since the end of the nineteenth century in Greenland, the Canadian Arctic, Svalbard, and the European Alps (Schwikowski et al., 1999). For example, trends of increasing SO_4^{2-} and NO_3^- over the 50–100 years leading up to the 1970s are evident in data from South Greenland (Figure 6; Mayewski et al., 1986, 1990). In the Alps, population centers are located close to ice core sites, and therefore determining the sources responsible for SO_4^{2-} and NO_3^- is relatively straightforward (Schwikowski et al., 1999). In the Arctic, long-range transport of pollutant aerosol makes source identification more difficult due to mixing. Different approaches have been used to distinguish source contributions, including statistical analysis and time-series correlation of spatially distributed records (Goto-Azuma and Koerner, 2001). Results suggest that it may be possible to separate multiple anthropogenic sources from different regions in a single ice core record through the use of stable isotopic analysis. Long-term records of possible anthropogenic impact on atmospheric SO_4^{2-} and NO_3^- in Asia do not exist, in part because of the masking effect from large terrestrial dust inputs. However, stable sulfur isotope ratios in Asian snow suggest that anthropogenic SO_4^{2-} can be distinguished (Pruett et al., 2004). At the present time, there is no convincing evidence for an anthropogenic impact on SO_4^{2-} or NO_3^- concentrations in Antarctica.

Introduction

Current Understanding of the CH₄ Cycle

Methane (CH₄) is a trace compound of the Earth's atmosphere with a globally averaged mixing ratio of 1800 ppbv, representing a total load of 5000 Tg (1 Tg = 10¹² g). It is removed from the atmosphere mainly (85–90%) through oxidation with the hydroxyl radical OH. The reaction rate between the two gases is slow enough so that the lifetime of CH₄ (time required to reduce its atmospheric mixing ratio by a factor *e*) today is 9.6 years. Therefore, differences of tropospheric mixing ratios as a function of latitude and longitude exist but are not more than typically 10% of the average. Five to ten percent of CH₄ is oxidized in the stratosphere and another 5% is oxidized in soils by methanotrophic archaea.

Under natural conditions, methane is mainly produced in the continental biosphere, through decomposition of organic matter under anoxic conditions. These conditions are met in wetlands, during the enteric fermentation in ruminants and in termites. In addition, CH₄ is produced during incomplete combustion of terrestrial biomass and by degassing of natural gas reservoirs (from coal and gas deposits, volcanoes and hydrates in permafrost). The world oceans are small contributors of CH₄ to the atmosphere (at the most 5–10 Tg year⁻¹). Methane then comes either from anoxic layers of the oceans or from hydrate degassing at the sediment/water interface. Altogether, the natural methane sources represent between 180 and 250 Tg year⁻¹, depending on the estimates. It was shown that CH₄ can also be directly produced by plants under oxic conditions (Keppler et al., 2006), but there is ongoing debate on the global strength of this source. A thorough review of the CH₄ cycle is provided in the IPCC AR4 report (Denman et al., 2007).

Reconstructing CH₄ Levels During the Quaternary

Although in the case of CO₂, other media – such as carbon isotopic ratios of organic compounds in bogs or boron isotopes in ocean sediments – are proposed to reconstruct its Quaternary trend, for CH₄ the only way to access its past mixing ratio is to measure it in bubbles trapped in polar ice sheets. Measurements can also be performed on ice from tropical glaciers but their interpretation is less straightforward due to local artifacts. Summer melting and percolation of the meltwater can modify the gas composition by solubility effect; and there are indications that methanogenesis by methanogenic archaea probably transported and deposited with atmospheric aerosols can also take place in these conditions (Campen et al., 2003).

Polar ice-core CH₄ records encompass now the last 800 000 years (Louergue et al., 2008). The time resolution of the records ranges from a decade (industrial increase) to a couple of millennia (oldest glacial–interglacial cycles in the available records). Different analytical techniques have been

applied for extracting the gas from the ice and quantifying the CH₄ content as well as its carbon and hydrogen isotopic ratios (see section 'Analytical Techniques'). The typical reproducibility obtained on replicate measurements of neighboring samples lies between 4 and 10 ppbv, that is, 1–3% of the maximum amplitude of mixing ratio changes. It usually amounts between 0.1 and 0.3‰ for ¹³C/¹²C and to 4‰ for D/H, that is, 5–25% of the full scale of CH₄ isotopic ratio changes measured so far.

The characteristics of the main ice-core drilling sites used for CH₄ studies are given elsewhere in this encyclopedia. Here, extra details on the firn densification process and gas diffusion are provided. They are crucial phenomenon to determine (1) the phasing between atmospheric composition changes, recorded in the bubbles, and the climate changes, recorded in the ice matrix, and (2) the smoothing of atmospheric variations during the gas trapping in the ice.

Ice forms in polar regions by compacting and then sintering of snow grains, under the weight of subsequently fallen snow. The speed of densification depends primarily on snow temperature and on accumulation rate at the surface. This leads to a firn/ice transition ranging between 60 and 120 m of depth below the surface and a Δ-age (mean difference of age between the trapped gas and the surrounding ice) of 30 years (present-day conditions at the high accumulation rate site of Law Dome, Antarctica) to more than 7000 years (very dry glacial conditions at Vostok, Antarctica). Based on current knowledge of the physics of snow and firn densification, it has been possible to develop models simulating the firn densification and Δ-age under various conditions. Uncertainties on past temperature and accumulation rates are the main factors limiting our ability to accurately calculate Δ-age in the past. At Greenland Ice Core Project (GRIP) and Greenland Ice Sheet Project 2 (GISP2) in Greenland, the uncertainty around Δ-age calculations is about 100 years. At EPICA Dome C (EDC, Antarctica) or Vostok, it amounts to about 1000 years. Empirical Δ-age evaluations at EDC and EPICA Dronning Maud Land (EDML, Antarctica) under glacial conditions suggest that the densification models tend to slightly overestimate the true Δ-age (Louergue et al., 2007), thus also questioning our understanding of physical processes at work during firnification under drier and colder conditions than today in the Antarctic plateau.

An analytical method developed in the 1990s provided an evaluation of the Δ-age independently from the firn densification models: it relies on the anomalies of permanent gas stable isotopic ratios (¹⁵N/¹⁴N of N₂, ⁴⁰Ar/³⁶Ar) in the bubbles, generated by abrupt temperature changes at the surface of the ice sheet. Temperature gradients between the atmosphere and the firn/ice transition produce gas thermal diffusion and fractionation of these isotopes with depth, as gases diffuse about ten times faster than heat in snow. It thus provides a climate record in the gas phase, shifted by Δ-age with the same record in the ice phase (water isotopes). The method

has been applied with success in Greenland where rapid and large temperature changes took place in the past (e.g., Landais et al., 2004; Severinghaus and Brook, 1999), but its application to Antarctica remains so far sporadic and difficult, due to the lack of rapid (decadal to centennial) and ample temperature changes in the past.

When bubbles are formed within an ice density range of 0.78–0.84 g cm⁻³, the age of the gas inside the bubble is not zero; air molecules must diffuse through the thick porous snow and firn column before getting trapped. It requires from 10 to 100 years for CH₄ molecules to diffuse from the atmosphere down to the closing bubbles in the firn. The diffusion process is mainly driven by the gradient of gas mixing ratio as a function of depth, by the tortuosity of the firn structure, and by temperature gradient between the surface and the firn/ice transition (Schwander, 1996). It is also influenced by gravitation, enriching the deepest portion of the firn with the heaviest gas compounds. For CH₄, gravitation reduces its mixing ratio at the base of the firn by only 0.7% at maximum compared with the atmosphere. This effect is thus neglected in most studies.

Air diffusion smooths out part of the atmospheric composition variability. On the Antarctic plateau for instance, the age distribution of air molecules (with respect to the first time when they crossed the atmosphere/surface snow boundary) at the base of the firn typically covers several decades. The progressive enclosure of bubbles in the density range 0.78–0.84 is another process smoothing atmospheric variations. This transition of density requires from 10 to 1000 years, depending on the accumulation rate. As a consequence, CH₄ records associated with rapid atmospheric changes and obtained from ice cores with different accumulation rates can significantly differ from each other. For instance a comparison between CH₄ records from the GRIP and EDC ice cores covering the methane drop associated with the rapid 8.2-ka BP cooling showed that the latter core attenuated the amplitude of the CH₄ drop by about 50% (Spahni et al., 2003). A precise quantification of this phenomenon under glacial conditions has yet to be performed.

The Last Millennium

Since the late 1980s, several ice-core records of the CH₄ mixing ratio have been obtained from Greenland and Antarctica covering the last millennium, depicting a relatively stable level around 700 ppbv followed by the dramatic anthropogenic increase over the last two centuries. As in the case of CO₂, using the most detailed and accurate record of Law Dome in Antarctica, ice-core measurements also cover the most recent time up to the late 1970s (MacFarling Meure et al., 2006), providing an excellent overlap with mixing ratios obtained on the Cape Grim air archive (pressurized tanks), and nicely extending the direct atmospheric measurements at South Pole. The overlap is confirmed by measurements of CH₄ in interstitial firn air at the same site. This is a clear indication that polar ice cores accurately record the atmospheric CH₄ mixing ratio.

The ~1100 ppbv increase of atmospheric CH₄ is accompanied by an increase of its ¹³C/¹²C stable isotopic ratio by about 2‰, and by about 15‰ for D/H of CH₄ (Figure 1). It traces the

increased ratio of average anthropogenic sources (rice cultivation, ruminants, landfills, biomass burning, coal and gas extraction, and distribution) over natural sources (Sowers et al., 2005).

The time period between AD 1000 and 1800 shows small but significant fluctuations of the CH₄ mixing ratio, both over Greenland and over Antarctica, with an amplitude of ~50 ppbv. They seem to be roughly correlated with the medieval warm period and the Little Ice Age, two climatic phenomena which could have directly affected natural sources such as biomass burning and wetlands, but also early anthropogenic sources. Measurements of the ¹³C/¹²C isotopic ratio of CH₄ over the last 2000 years reveal an enrichment by about 2‰ between AD 0 and 1000 compared with the time period AD 1700–1900, whereas the CH₄ mixing ratio does not show concomitant and large changes (Ferretti et al., 2005; Mischler et al., 2009). A parallel enrichment of D/H (by about 10‰) is also observed (Mischler et al., 2009). This is interpreted as an increased contribution of biomass burning emissions to the CH₄ budget (and contemporary reduced wetland emissions) during the earlier period. Agricultural sources of CH₄ would have progressively increased with time. An alternative explanation of the parallel evolution of CH₄ and its ¹³C/¹²C isotopic ratio could be related to the proposed CH₄ production by plants and changes of primary productivity during the last two millennia (Houweling et al., 2008; Kepler et al., 2006). However, recent investigations of carbon monoxide mixing ratio and isotopic ratio changes (tracing different sources including biomass burning) recorded in Antarctic ice cores over the last millennium reinforce the scenario of large biomass burning emission changes controlling the millennial CH₄ evolution, at least in the Southern hemisphere (Wang et al., 2010).

The Holocene

High-resolution CH₄ records have been obtained over the Holocene from many Antarctic (D47, Byrd, Taylor Dome, EPICA cores, Talos Dome) and Greenland (GRIP, GISP2) ice cores (e.g., Blunier et al., 1995; Brook et al., 1999; Chappellaz et al., 1997; Schilt et al., 2010). They all show a much larger amplitude of change than during the last millennium: methane peaks at an average of ~700 ppbv during the early Holocene (10 000–11 500 years BP) and again during the last millennium. In between, it shows lower levels, with a minimum of ~570 ppbv centered at 5200 years BP (Figure 2). In addition, a decrease by ~80 ppbv is observed 8200 years ago, lasting about 300 years and synchronous with an abrupt cooling event recorded at the same time in the northern hemisphere (Spahni et al., 2003).

The comparison between Greenland and Antarctic records allows one to quantify the inter polar CH₄ difference. This difference results from the uneven distribution of CH₄ sources with latitude and from the fact that the residence time of methane in the atmosphere is only about ten times longer than the average atmospheric exchange time between the two hemispheres. Over the Holocene, on average, the inter polar difference amounts to 44 ± 7 ppbv but it also shows significant variations of the order of 10 ppbv. When translated into a

Figure 1 Atmospheric CH₄ evolution over the last millennium from the Law Dome (Antarctica) ice cores (black circles; MacFarling Meure et al., 2006). Black triangles correspond to observations on pressurized tanks of the Cape Grim air archive; the black line runs through NOAA/CMDL atmospheric measurements performed at the South Pole. Blue and red diamonds indicate D/H and ¹³C/¹²C changes in atmospheric CH₄, respectively, measured along the WAIS Divide ice core (Antarctica; Mischler et al., 2009). Orange circles are ¹³C/¹²C changes measured on the Law Dome ice cores (Ferretti et al., 2005). The upper three graphs show the concomitant evolution of the CO mixing ratio in Antarctica (black symbols) as well as its ¹³C/¹²C (red symbols) and ¹⁸O/¹⁶O (blue symbols) changes (Wang et al., 2010). 1994 values are indicated with the squared symbol. CO affects the oxidative capacity of the atmosphere (and thus the CH₄ budget) and shares biomass burning as a common source with CH₄. Error bars are 1σ uncertainties. Each record is on its own time scale.

simple three-box model of the atmosphere, the Holocene variations of the CH₄ inter-pole difference suggest that tropical sources (possibly tropical wetlands and biomass burning) dominated the Holocene CH₄ budget and that northern

sources would have contributed to the higher mixing ratios of the early Holocene (Brook et al., 1999; Chappellaz et al., 1997). The CH₄ increase occurring mainly during the last 2500 years, combined with a reduced inter-pole gradient during

Figure 2 CH₄ mixing ratio over the Holocene, measured on Greenland (GRIP) and Antarctic (D47 and Byrd) ice cores. The shaded area depicts the inter-polar CH₄ gradient. Its average evolution through time is shown in the lower panel with 1 σ error bars (red: Chappellaz et al., 1997; blue: Brook et al., 1999, using the Greenlandic GISP2 and Antarctic Taylor Dome ice cores). Upper panel: blue and red diamonds indicate D/H and ¹³C/¹²C changes in atmospheric CH₄, respectively, measured along the GISP2 ice core (Greenland; Sowers, 2010). Error bars are 1 σ uncertainties. Each record is on its own time scale.

the last millennium, suggests that early anthropogenic emissions (through rice cultivation, livestock and human-induced biomass burning) could have already significantly contributed to the preindustrial CH₄ budget (Chappellaz et al., 1997; Ruddiman and Thomson, 2001).

Recent investigations of the CH₄ stable isotopic ratios over Greenland and covering the Holocene period provide an additional story about the possible mechanisms involved. A progressive decrease of the ¹³C/¹²C isotopic ratio (by about 2‰) with time could reflect a growing contribution of Arctic

ecosystems relatively depleted in ^{13}C , and/or a progressive shift from C4 to C3 dominating plants in wetlands (Sowers, 2010). The D/H evolution of atmospheric CH_4 bears more sample-to-sample variability but mostly shows a $\sim 20\%$ positive shift between 4000 and 1800 years BP (Figure 2). Potential candidates to explain this trend are a shift to stronger CH_4 emissions from the tropics in recent times, or a gradual release of marine clathrates enriched in D versus H (Sowers, 2010).

The Last Glaciation and Deglaciation

Very detailed CH_4 records (with a time resolution reaching two or three decades at specific periods for some cores) have been obtained from the GRIP, GISP2, and NorthGRIP ice cores in Greenland, and the Byrd, EDC, EDML, Vostok, Dome Fuji, Taylor Dome, Siple Dome, and Talos Dome in Antarctica, covering the last glaciation and deglaciation. The warming of the last deglaciation is associated with the largest observed increase of atmospheric CH_4 since the last glaciation. It doubles over Greenland, starting from an average of 365 ± 7 ppbv between 17 000 and 20 000 years BP, and reaching an average of 718 ± 3 ppbv between 11 500 and 9500 years BP. No significant inter polar gradient (-3 ± 4 ppbv) is observed during the minimum of the Last Glacial Maximum (Dällenbach et al., 2000).

The four distinct intervals punctuating the CO_2 increase during the deglaciation find counterparts in the CH_4 trend. Methane levels start to increase at 17 000 years BP, in synchronicity with CO_2 . After a slow increase of ~ 100 ppbv until 14 500 years BP, its mixing ratio suddenly increases by another ~ 200 ppbv within 100 years. It then remains at ~ 650 ppbv during the entire Bolling/Allerød warm period. The following time interval, corresponding to the Younger Dryas cold period, is accompanied by a CH_4 drop of comparable amplitude and speed as the first rapid increase; the Younger Dryas ends with again a ~ 200 ppbv CH_4 increase within 100 years, leading to the early Holocene maximum of ~ 700 ppbv. A direct time comparison of the rapid CH_4 changes of the deglaciation with thermal anomalies in permanent gas isotopes has shown that the start of the CH_4 and Greenland climate events is synchronous or with a small delay of CH_4 by a maximum of 30 years (Severinghaus and Brook, 1999). On the other hand, the duration of the change is longer for methane than for Greenland temperature.

The remarkable correspondence between atmospheric CH_4 changes and Greenland climate fluctuations during the last deglaciation is indeed a feature characterizing the last glaciation (Figure 3). Each of the Dansgaard/Oeschger events recorded in Greenland ice has a counterpart in atmospheric CH_4 levels, although with a variable relationship in terms of amplitude (Brook et al., 1996; Chappellaz et al., 1993b). The CH_4 variations cover a range from 50 to 200 ppbv. As in the

Figure 3 Lower curve: CH_4 mixing ratio recorded in Greenland ice, over the last deglaciation and back to 78 000 years BP. Methane data are from GISP2 (gray: Blunier and Brook, 2001), GRIP (black: Blunier and Brook, 2001, compiling data from earlier papers; and green: Flückiger et al., 2004), and NorthGRIP (blue: Flückiger et al., 2004 and red: Huber et al., 2006). Ages have been transferred approximately to the NorthGRIP GICC05 age scale using matches between GRIP and GISP2, and between GRIP and NorthGRIP (Wolff et al., 2010). Upper curve: climatic record in Greenland reconstructed from the water isotopes. The numbers indicate Dansgaard/Oeschger events. YD means Younger Dryas. B/A means Bolling/Allerød. Adapted from Wolff EW, Chappellaz J, Blunier T, Rasmussen S, and Svensson A (2010) Millennial-scale variability during the last glacial: The ice core record. *Quaternary Science Reviews* 29 (21–22): 2828–2838.

case of the last deglaciation, each Dansgaard/Oeschger warming which has been investigated both for CH₄ and thermal anomalies of permanent gas isotopes indicates that the start of each phenomenon is in phase.

The modulation of CH₄ average amplitude throughout the last glaciation bears resemblance with the summer insolation curve at northern tropical latitudes (Flückiger et al., 2004). On the other hand, the average inter polar CH₄ gradient calculated over multiple Dansgaard/Oeschger events suggest that some of these events involved an increased CH₄ emission at boreal latitudes (Dällenbach et al., 2000). Few attempts have been made to quantify the CH₄ budget of the last glaciation maximum and the Holocene, and none during Dansgaard/Oeschger events. Two estimates of the global wetland extent and associated CH₄ emissions reach conflicting conclusions: a reduction of their extent by 50% (Chappellaz et al., 1993a) or an increase by 15% (Kaplan, 2002; Kaplan et al., 2006) during the Last Glacial Maximum compared to the preindustrial Holocene. But they reach a better agreement on the CH₄ emissions, with a reduction of 35 and 24%, respectively. Both studies conclude that other mechanisms than wetland extent and emission changes have probably contributed to the methane variability at glacial–interglacial time scale. One of the candidates is an increased oxidative capacity of the atmosphere during glacial times, reducing the CH₄ residence time in the atmosphere. Calculations of the OH concentration, taking into account the reduced sources of CH₄ and other organic compounds emitted by the biosphere, suggest that OH levels were 25% larger during glacial times (Kaplan et al., 2006; Valdes et al., 2005).

As for younger time periods, CH₄ stable isotopic ratio changes are a powerful means to evaluate different scenarios able to explain the CH₄ doubling during the deglaciation or its large changes associated with Dansgaard/Oeschger events. Combining ¹³C/¹²C, D/H and the inter polar gradient information, a plausible scenario is that the boreal wetlands were essentially switched-off during the Last Glacial Maximum and considerably developed during the deglaciation. On the other hand, biomass burning would have remained nearly constant at global scale throughout the glacial–interglacial transition (Fischer et al., 2008). For the few investigated Dansgaard/Oeschger events, methane stable isotopes suggest that boreal wetlands were again the main trigger of the concentration increase (Bock et al., 2010). The hypothesized catastrophic degassing of methane hydrates suggested from marine records seems to be ruled out by the evolution of D/H of atmospheric CH₄ (Bock et al., 2010).

As methane is well recorded both in Greenland and Antarctic ice, shows rapid changes, and is a signal of global significance (i.e., its changes are synchronous at a global scale), it provides an excellent tool to put ice cores from different places on a common relative time scale. Provided that the Δ -age is calculated with sufficient precision, the phase relationship between climate records from different ice cores can then be determined with a precision reaching in the best case about 200 years. This method, pioneered by Blunier et al. (1997) when they showed that the Antarctic Cold Reversal was synchronous with the Bolling/Allerod warm period in Greenland, has been applied to the Dansgaard/Oeschger events of the last glacial (Blunier and Brook, 2001; Blunier et al., 1998; Brook

et al., 2005; EPICA Community Members, 2006). It reveals that each major Dansgaard/Oeschger warming recorded in Greenland is associated with the start of a cooling trend in Antarctica. This important finding for climate dynamics is a clear demonstration of the existence of the bipolar seesaw phenomenon of energy redistribution between the two poles associated with the strengthening or weakening of the North Atlantic thermohaline circulation.

The Last Eight Glacial–Interglacial Cycles

The first ice core giving access to the atmospheric methane variability in the course of several glacial–interglacial cycles was the Vostok one (Chappellaz et al., 1990; Delmotte et al., 2004; Petit et al., 1999). Covering the last 420 000 years, it indicates that CH₄ levels naturally fluctuated in a range between 320 and 800 ppbv, that is, largely below its present-day level of 1800 ppbv. The methane trends are highly correlated with Antarctic temperature changes, with highest mixing ratios during interglacial times and lowest ones during the glacial maxima. All deglaciations depict a similar trend of the CH₄ increase, in two steps: after a slow increase over a few millennia, a rapid increase over one to three centuries takes place. On the other hand, methane closely follows Antarctic temperature during the glacial inception and does not show a lag as observed for CO₂. The periodicities characterizing insolation changes at the Earth's surface are imprinted in the CH₄ record: the largest variance is associated with the 100 000-year periodicity but with significant parts of the variance being associated with the 40 000-year and 23 000/19 000-year periodicities. The calculated direct radiative impact of the glacial–interglacial CH₄ changes implies a mean global temperature increase (including chemical feedbacks on methane, i.e., tropospheric ozone and stratospheric water vapor, but excluding other climate feedbacks) of ~ 0.10 °C.

In addition to the low-frequency variability, the Vostok methane record also depicts millennial-scale changes during previous glaciations, comparable with variations observed during the Dansgaard/Oeschger events of the last glaciation (Delmotte et al., 2004). This suggested that abrupt climatic changes during glaciations are a robust feature of the late Quaternary.

The Vostok CH₄ record has been confirmed over the last three climatic cycles with the Japanese Dome Fuji ice core. In 2005, the newly available EDC ice core has allowed one to extend the Vostok record back to 800 000 years, that is, four additional glacial–interglacial cycles (Louergue et al., 2008; Spahni et al., 2005). Before 420 000 years BP, the EDC climate record is characterized by milder and longer interglacials compared with the more recent ones. The atmospheric CH₄ mixing ratio indicates a similar trend, with relatively lower (~ 600 ppbv) and longer maxima during the two older interglacials (Figure 4). The extended record shows that the precessional component of orbitally-induced CH₄ variability bore a stronger contribution during the four more recent climatic cycles. It also reveals that millennial-scale CH₄ variability is ubiquitous of the last eight glaciations. Although a quantitative and mechanistic link between climate and methane changes on such time scale is not yet available, the observation of a similar relation of proportionality throughout eight climatic cycles between Antarctic

Figure 4 Evolution of the CH₄ mixing ratio over the last 800 000 years, compared with the D/H Antarctic temperature proxy. Data from Loulergue et al. (2008) and Jouzel et al. (2007).

temperature and atmospheric CH₄ levels suggests that the mechanisms involved are persistent and robust.

Analytical Techniques

To measure CH₄ in ice cores, the extraction of trapped gases can be performed using a dry extraction method, provided that there is no friction between metal parts within the extracting device. These frictions usually degas significant and variable amount of methane. Only the 'cheese grater' technique has proved to deliver CH₄ mixing ratios with negligible contamination from the extraction chamber (Etheridge et al., 1998).

Instead, the most popular technique consists in melting the ice sample (typically 40–50 g) under vacuum and subsequently refreezing the melt water from the bottom part of the container, in order to expel the dissolved gases. Containers are usually made of glass, but stainless steel is also used (Sowers et al., 1997).

A sublimation technique has also been developed and applied to CH₄ in ice cores (e.g., Güllük et al., 1998). It gives good agreement with the melting–refreezing method but its complexity does not justify a routine application for methane alone.

Then the gas is expanded in a sample loop and injected in the analytical instrument, or eventually purified on cold traps where only CH₄ is retained.

The detection and quantification of CH₄ in the gas stream from the sample loop or cold traps is obtained by gas chromatography, using a flame-ionization detector. Calibration of the instrument is performed for each extraction against standard gases of known CH₄ mixing ratio.

Recently, a new method has been developed where CH₄ is measured by gas chromatography downstream from a

continuous-flow analysis system initially built for chemical analyses of ice cores (Schüpbach et al., 2009). It provides a nearly continuous methane record along ice cores, with a much larger sample throughput than discrete sample techniques, but with a lower accuracy. The best results are now expected to come soon from the coupling between continuous-flow extraction techniques and new optical detectors to accurately measure the CH₄ mixing ratio in air.

Stable isotopic ratios of CH₄ are measured using gas chromatography, followed by on-line combustion of CH₄ to CO₂ under helium flow, and introduction into a magnetic-sector isotopic ratio mass spectrometer. Due to the small signal to decipher, it requires larger ice sample size: typically a few hundred grams for each measurement.

Introduction

Mountain glaciers, small ice caps, and the two large ice sheets in Greenland and Antarctica arguably contain the highest temporal resolution and most direct paleoenvironmental archives available for the Quaternary. Impurities scavenged from the atmosphere by falling snow and deposited directly by gravitational settling comprise a highly detailed record of past changes in climate and anthropogenic impacts – including atmospheric composition (e.g., Mayewski et al. (1993) and BOUTRON et al. (1994)), oceanic and atmospheric circulation (e.g., Mayewski et al. (1994) and Delmonte et al. (2004)), meteorology (e.g., Alley et al. (1993)), explosive volcanism (e.g., Robock and Free (1996)), marine and terrestrial biosphere emissions (e.g., Legrand et al. (1991)), biomass burning (e.g., Holdsworth et al. (1996)), and industrial pollution (e.g., Davidson et al. (1991), BOUTRON et al. (1994), and Wolff and Suttie (1994)). The challenge is for Earth scientists to strategically sample and analyze the unique glaciochemical archive as well as comprehensively interpret the history contained therein.

Ice cores collected from glaciers, ice caps, and ice sheets are used to investigate the glaciochemical record. Cores from high-snowfall regions reveal annual layers that are easily distinguished by their chemical characteristics (e.g., McConnell et al. (2002)). Sampling of cores from these regions is often designed to yield glaciochemical records with 20 or more samples per year. These high-resolution records span recent decades to a few millennia and have been developed from cores collected in high-snowfall regions in Greenland, Antarctica, and a number of mountain glaciers and ice caps (e.g., Kreutz et al. (2000) and Correia et al. (2003)). The longest glaciochemical records – possibly spanning up to a million years – are available only from low-snowfall, high-latitude regions of Antarctica. Because of the low snowfall at these sites, temporal resolution is limited and annual layering is not preserved in the longest records.

Extent of the Glaciochemical Archive

Glaciers and small ice caps outside of Antarctica have a combined area of about 0.54 million km² (Intergovernmental Panel on Climate Change, 2001). While located at most latitudes, they are found only at very high elevations in the low and mid-latitudes. Glaciochemical records developed from cores drilled to bedrock in these regions typically span hundreds to thousands of years; some records are as long as 15 ka (e.g., Thompson et al. (1995); see South America; Chinese, Tibetan Mountains; Africa.

The Greenland ice sheet covers 1.71 million km² and lies between 60° and 82° N latitude (Intergovernmental Panel on

Climate Change, 2001). Because snowfall rates are relatively high over much of Greenland, ice cores drilled to bedrock typically span tens of thousands to hundreds of thousands of years. To date, five ice cores have been collected to bedrock in Greenland. The longest of these Greenland records are from the ~3200-m-long European Greenland Ice Sheet Project (GRIP, 72.6° N, 37.6° W) and US Greenland Ice Sheet Project 2 (GISP2; 72.6° N, 38.5° W) cores which were drilled near the summit of the ice sheet in the early 1990s. These high-resolution records span more than 250 ka, with annual layering identified for the past 110 ka.

The Antarctic ice sheet has an area of 12.37 million km² (Intergovernmental Panel on Climate Change, 2001). With an area half the size of North America, the Antarctic ice sheet and smaller glaciers and ice caps in Antarctica extend from 67° S at the tip of the Antarctic Peninsula to 90° S at the South Pole. Several cores reaching bedrock have been collected in Antarctica including the Vostok (78.5° S, 106.8° E), EPICA Dome C (81.7° S, 148.8° W), and Dome Fuji (77.3° S, 39.7° W) cores in East Antarctica and the Siple Dome core (78.5° S, 106.8° W) in West Antarctica. The longest record is from Dome Fuji, which, although not yet confirmed, may span 1000 ka.

Aerosols and Microparticles

Impurities contained in glacier ice include gases trapped in air bubbles, soluble gases, and acids adsorbed or dissolved in the ice, and soluble and insoluble impurities from aerosols – particulate matter suspended in the air. The focus here is on impurities from atmospheric aerosols which form soluble and insoluble microparticles when found in glacier ice. Natural sources of aerosols include sea spray, volcanic emissions, forest and grassland fires, mineral dust, and biogenic emissions. Aerosols also result directly from human activities including burning of fossil fuels and biomass burning to clear land, and indirectly from land-use changes which expose soil to wind erosion (e.g., Tegen et al. (1996) and Prospero et al. (2002)).

Aerosols are an important part of the Earth system, influencing critical environmental processes such as biogeochemical cycling and climate forcing. For example, soluble iron (Fe) in dust is an important fertilizer of the remote oceans with increased dust flux linked to new phytoplankton production and carbon sequestration in Fe-limited regions such as the Southern Ocean and northern Pacific (Martin, 1990). Since aerosols also affect the Earth's radiation balance (e.g., Intergovernmental Panel on Climate Change (2001), Menon et al. (2002), and Tegen et al. (1996)), investigating how aerosol characteristics and concentrations vary in the atmosphere today and how they might have varied in the past is crucial to

understanding the Earth system and how it will evolve in the future. As with modern studies of airborne aerosols (e.g., Rahn and Lowenthal (1985)), rock type and chemical composition of insoluble microparticles found in different layers of ice within a glacier provide important information on the origin of these microparticles.

Microparticles in glacier ice are both soluble and insoluble, with most being soluble. Soluble microparticles include sea salts, sulfate aerosols from volcanic and marine biogenic emissions, and some terrestrial dusts such as carbonates from evaporite deposits. Insoluble microparticles are composed of crustal materials including aluminosilicate rock dust, with lesser amounts from volcanic shards and extraterrestrial material. The ratio of soluble to insoluble fractions of elements measured in glacier ice varies with the location and depth of the ice cores. For example, calcium (Ca) found in central Greenland ice comes primarily from continental dust, with the soluble form associated with sea salt, calcium carbonate, and dolomite dust. The insoluble fraction is primarily from apatite and plagioclase minerals. Laj et al. (1997) found that the soluble fraction of Ca in the GRIP core varied from 30% to almost 100% during the past 110 ka, with a high fraction of soluble Ca during cold periods when total Ca concentrations were high.

Sources of Microparticles in Glacier Ice

Most elements in microparticles archived in glacier ice have multiple sources. For example, magnesium (Mg) is found in large quantities in sea salt as well as evaporite and aluminosilicate dust. It also may occur in lesser amounts in volcanic and forest fire ash, as well as pollution aerosols. Similarly, lead (Pb) is found in rock dust but is generally heavily enriched even in preindustrial aerosols, probably as a result of adsorption of Pb from quiescent volcanic emissions (Matsumoto and Hinkley, 2001) and early metal smelting (Boutron et al., 1994). Since industrialization, Pb in the atmosphere and glacier ice has been dominated by industrial pollution. Fully interpreting an elemental record of Mg or Pb requires simultaneous measurement of a range of other elements or chemical compounds to elucidate all possible sources.

Ice-Core Research Results

The number of glaciochemical studies of microparticles in ice cores that have been conducted since the 1980s is very large, particularly those focused on soluble microparticles (e.g., Mayewski et al. 1993, 1994 and De Angelis et al. (1997)). A complete review is far beyond the scope of this contribution. Instead, the following addresses selected ice-core research results organized into two overlapping themes: (1) dust provenance in Greenland and Antarctica and (2) heavy metal pollution in central Greenland. These themes, and the studies selected to illustrate them, reflect the potential of ice-core research to address critical issues in climate change and anthropogenic impacts. Although not exhaustive, the examples reveal new methods' development, creative approaches to interpreting data, and, perhaps most significantly, the complexity and

interrelationships that must be considered in interpreting results of ice-core studies.

Fingerprinting Microparticle Provenance in Central Greenland and East Antarctica

The mineralogy of rocks as well as elemental and isotopic ratios in dust derived from these rocks varies naturally from region to region around the world. Elemental and isotopic ratios in industrial emissions and volcanic tephra vary as well. Together, these often-subtle variations provide a means to fingerprint the source region (or provenance) of dust, volcanic tephra, and pollution aerosols. Knowledge of provenance leads to a better understanding of atmospheric circulation and how it may have changed in the past.

Satellite-based studies indicate that topographic lows with large accumulations of fine particles easily eroded by wind are the primary sources of dust aerosols today. Many of these alluvial sediment deposits were formed during the late Pleistocene or Holocene, and most are found in low- to mid-latitude regions such as northern Africa, central Asia, and Australia, with higher-latitude sources in southern South America and southern Africa (Prospero et al., 2002). Dust aerosols found in most polar ice cores have been transported over very large distances since the cores are usually located in the interior of the ice sheets, well away from any local dust sources. Conversely, dust aerosols found in Alpine cores are often a combination of proximal and distal sources. Distinguishing the source can be difficult, with one method – use of isotopic ratios – applied in some studies.

Isotopic ratios have been used extensively to determine the provenance of dust in deep ice cores and provide a demonstration of the use of trace element analyses of microparticles for determining provenance. Building on earlier studies in Antarctica, Biscaye et al. (1997) analyzed Pb, strontium (Sr), and neodymium (Nd) isotopes in microparticles filtered from GISP2 ice-core samples to determine the source region for dust deposited during the last glacial period. The measured ratios were compared to similar measurements of particles less than 5 μm in diameter from possible source areas (PSAs) in North America, Asia, and Africa. Based on the isotopic ratios, Biscaye and his colleagues were able to exclude mid-continental North America and Africa as source regions, and concluded that eastern Asia was the likely source of terrestrial dust deposited in central Greenland during the last glacial period.

Basile et al. (1997) used similar measurements of Sr and Nd isotopes in the Vostok and old Dome C ice cores to evaluate the provenance of dust during the last three glacial periods in East Antarctica. Comparisons to similar measurements from PSA in Antarctica, New Zealand, Australia, South America, and southern Africa indicated that South America – specifically, Patagonian loess – was the source. Delmonte et al. (2004) expanded this research to include the new EPICA Dome C core and far more samples of dust from possible source areas of the Southern Hemisphere. In agreement with the earlier study, Delmonte and her colleagues concluded that a broader region in South America – including Patagonia but also the Pampas and possibly the continental shelf of Argentina exposed by lower sea level – was the provenance of the dust at the two

Figure 1 $^{87}\text{Sr}/^{86}\text{Sr}$ versus $\epsilon_{\text{Nd}}(0)$ fields for (a) dust measured in the Dome C and Vostok ice cores; and (b) as in (a) but with similar measurements of samples from possible source areas throughout the Southern Hemisphere. Note the difference in the vertical axes. Samples from possible sources areas were limited to $<5 \mu\text{m}$ since this size range is subject to long-range transport in the atmosphere. Reprinted from Delmonte B, Basile-Doelsch I, Petit J-R, et al. (2004) Comparing the Epica and Vostok dust records during the last 220 000 years: Stratigraphical correlation and provenance in glacial periods. *Earth-Science Reviews* 66: 63–87, Copyright 2004, with permission from Elsevier.

ice-core sites. Similarities to the Sr and Nd isotopic signatures for Antarctica (Dry Valleys) and New Zealand, however, indicate that these regions also may be sources for some of the dust found in East Antarctica (Figure 1).

Evaluation of Heavy Metal Pollution in Central Greenland

Microparticles deposited in glacier ice reflect aerosol composition of the local atmosphere as well as aerosol composition and atmospheric chemistry along the trajectory of air parcels arriving at an ice-core site, particularly moisture-bearing air parcels (Davidson et al., 1991). Many ice-core chemistry studies are aimed at reconstructing how atmospheric composition has changed in the past as a result of climate change, volcanic eruptions, or industrial pollution. For example, Mayewski et al. (1993) used measurements of soluble major ions in the GISP2 ice core in Greenland to evaluate changes in atmospheric composition around the Younger Dryas, a period of rapid climate change which occurred during the transition from the last glacial period to the Holocene some 12–13 ka BP.

Because long-range transport results in widespread contamination, many studies have used measurements of heavy metals in well-dated glacier ice to document changes in industrial pollution of the remote Arctic from recent decades to several centuries ago (Boutron et al., 1994; Davidson et al.,

1991). In most of these studies, total concentrations were measured, including both soluble and insoluble fractions. Lead was the focus of many of the early studies, in part because of the very dramatic increases in emissions associated with leaded gasoline use in automobiles, coordinated government efforts to eliminate Pb emissions (e.g., the U.S Clean Air Act implemented in the early 1970s), and well-defined concerns for human and ecosystem health. Ice-core studies document a tenfold increase of Pb deposition in parts of Antarctica and up to a 200-fold increase in central Greenland (Boutron et al., 1994; Wolff and Suttie, 1994).

Heavy metal concentrations in Antarctic snow and ice are exceedingly low, often in the fg g^{-1} to pg g^{-1} levels ($1 \text{ fg} = 10^{-15} \text{ g}$; $1 \text{ pg} = 10^{-12} \text{ g}$; $1 \text{ ng} = 10^{-9} \text{ g}$; $1 \mu\text{g} = 10^{-6} \text{ g}$). With recent advances in analytical capabilities, however, the number and scope of ice-core studies of heavy metal pollution have increased dramatically. For example, no recent trends were observed in some metal concentrations – including manganese (Mn), cobalt (Co), and vanadium (V) – in ice-core samples from Coats Land, Antarctica. Recent increases were observed in the same samples, however, for chromium (Cr), copper (Cu), zinc (Zn), Pb, and uranium (U). Planchon et al. (2002) attributed these increases to nonferrous mining and smelting in South America, southern Africa, and Australia.

Figure 2 A 330-yr continuous ice-core record of Pb concentration, flux, and relative enrichment at the D5 ice-core site (68.5° N, 42.9° W) in west central Greenland. Shown are annual average values determined from high-resolution measurements (>40 samples yr^{-1}). Enrichment was calculated using core-registered measurements of the crustal dust tracer Al.

Related studies have been conducted in Alpine regions (Kreutz et al., 2000; Correia et al., 2003) and Greenland as well. For example, Barbante et al. (2001) investigated pollution in Greenland from platinum group metals (PGMs) that are emitted from aging catalytic converters on automobiles. They reported concentrations 40 to 120 times higher in 1990–95 snow than in ice deposited ~ 7 ka, suggesting that PGM pollution is indeed widespread. Also, a high-resolution ice-core record of Pb concentrations, fluxes, and crustal enrichments (relative to aluminum, a crustal dust tracer) demonstrates how Pb pollution has varied in west central Greenland during the past 330 yr (Figure 2).

Specifically, Pb concentration and flux were low but slowly rising prior to widespread industrialization in the mid-1800s. Fluxes increased from $\sim 1.5 \mu\text{g m}^{-2} \text{yr}^{-1}$ in 1670 to $\sim 5 \mu\text{g m}^{-2} \text{yr}^{-1}$ in 1860, and enrichment rose slowly as well. Increases in Pb deposition lasting from a few months to a few years resulted from fallout from explosive volcanism. Beginning in ~ 1865 , Pb flux increased dramatically and reached $\sim 37 \mu\text{g m}^{-2} \text{yr}^{-1}$ by 1895, more than a sevenfold increase from pre-1865 levels. Following the sharp, well-defined drop during the Great Depression when fluxes declined to $\sim 17 \mu\text{g m}^{-2} \text{yr}^{-1}$, fluxes increased rapidly from 1939 to a peak in 1970 of more than $120 \mu\text{g m}^{-2} \text{yr}^{-1}$, a 24-fold increase from pre-1870 levels. By 1985, Pb deposition had declined to $\sim 20 \mu\text{g m}^{-2} \text{yr}^{-1}$ in response to government-mandated emission reductions. Mean annual fluxes from 1985 to 2002, however, were still 200% of those observed prior to 1865 and 700% of those observed in 1670. Relative enrichment of Pb with respect to the crustal dust tracer aluminum (Al) provides a similar story since Al concentrations have not changed

significantly during this time period. While the drop in Pb pollution from ~ 1970 to ~ 2000 closely matches similar declines in estimated US industrial emissions (McConnell et al., 2002), industrial emissions were orders of magnitude greater during the era of leaded gasoline use in automobiles than before. As Figure 2 clearly shows, however, Pb pollution in west central Greenland during the leaded gasoline era was only about twice that observed at the beginning of the twentieth century, some three decades before the widespread use of leaded gasoline. It is clear that much of the Pb pollution found in Greenland ice cores comes from other sources such as smelting and coal combustion, although the exact sources remain unknown.

Conclusions and Future Directions

Glaciochemical records developed from ice cores collected from mountain glaciers and the polar ice sheets are a cornerstone of environmental and climate change research. Chemical, elemental, and isotopic measurements of soluble and insoluble microparticles in ice cores can be used to develop highly detailed records of change in atmospheric composition, atmospheric circulation, and source areas during the past hundreds of thousands of years. Advances in analytical methods mean that even more detailed environmental records will be obtained from ice cores in the future, leading to a better understanding of the Earth system and the impacts of human activities. Future emphasis on ice-core arrays to better define spatial distribution patterns and application of high-resolution analytical methods will increase the validity of ice-core

research results and support more sophisticated interpretation of atmospheric and ocean circulation patterns.

Introduction

Stable isotope ratios measured in ice ($^{18}\text{O}/^{16}\text{O}$ and D/H) provide some of the most fundamental data sets for ice-core paleoclimatology. This field was pioneered in Greenland in the 1960s by Dansgaard and colleagues and the classic paper outlining why stable isotopes in ice are affected by temperature change was published by Dansgaard in 1964. Since then stable isotope records have been measured for virtually all ice cores collected, providing a rich data set with which to understand the controls on the isotope ratios and what they can tell us about past environmental conditions. This is a large field, and this review attempts to summarize the important points necessary for understanding isotopic time series from polar ice-core records. Processes affecting ice-core records from tropical and temperate glaciers can be significantly different than for polar sites, and are discussed in separate articles on cores from such sites.

Standard Notation and Measurements

The stable isotope pairs normally measured in ice cores are $^{18}\text{O}/^{16}\text{O}$ and D/H of water. The majority of natural water molecules contain the lighter isotopes (e.g., H_2^{16}O). Heavier forms are present in small but measurable amounts. H_2^{18}O is approximately 0.2% of the total in natural waters, and HD^{16}O is less than 0.1%, but varies widely due to the influence of the large relative mass difference between D and H on isotopic fractionation between liquid, vapor, and solid (Faure, 1986). D_2O is present, but in very small quantities, as are forms containing ^{17}O , which is not normally measured in this application. In recent ice-core literature $^{18}\text{O}/^{16}\text{O}$ and D/H of ice are sometimes referred to as 'water isotopes' to distinguish them from isotopes of gases in air bubbles. These ratios are measured by standard dual inlet gas source isotope ratio mass spectrometry. Oxygen isotopes are normally measured by equilibrating the water with carbon dioxide (CO_2) with known oxygen isotope ratio. Through isotope exchange reactions the CO_2 takes on the isotope ratio of the water in a quantifiable way, and the CO_2 gas is inlet to the mass spectrometer for measurement. D/H ratios are measured after converting the water to hydrogen gas by reduction over hot metal. In both cases the sample ratios are repeatedly measured relative to a standard to obtain the high precision needed. The normal standard used for virtually all ice-core measurements is maintained by the International Atomic Energy Agency and called Vienna Standard Mean Ocean Water (V-SMOW). The D/H ratio for V-SMOW is 155.75×10^{-6} and the $^{18}\text{O}/^{16}\text{O}$ ratio is 2005.2×10^{-6} .

Natural water and ice vary by small amounts relative to these values. For this reason isotope ratios are expressed in

'delta' notation, in units of parts per thousand, or 'per mil' (‰) as follows:

$$\delta^{18}\text{O} = \frac{(^{18}\text{O}/^{16}\text{O}_{\text{sample}}) - (^{18}\text{O}/^{16}\text{O}_{\text{standard}})}{(^{18}\text{O}/^{16}\text{O}_{\text{standard}})} \times 1000,$$

or

$$\delta\text{D} = \frac{(\text{D}/\text{H}_{\text{sample}}) - (\text{D}/\text{H}_{\text{standard}})}{(\text{D}/\text{H}_{\text{standard}})} \times 1000$$

In general, polar ice is depleted in the heavy isotope with respect to seawater, for reasons outlined below, making delta values for ice-core samples negative. δD and $\delta^{18}\text{O}$ have been measured somewhat interchangeably over the history of ice-core research, primarily as a matter of convenience, but the combination of the two measurements provides additional information, as described in the section below on deuterium excess.

Basic Theory and Observations of Modern Isotope Distribution in Polar Regions

As mentioned above, stable isotope records have utility in ice-core studies for both paleothermometry and stratigraphy. The dependence of $\delta^{18}\text{O}$ and δD values on temperature in polar regions is commonly accepted, but the origin of this dependence is indirect, rather than arising from a simple temperature dependence of equilibrium isotopic fractionation in a chemical reaction, and is complicated by several factors. To start with, a simple picture, derived from the work of Dansgaard et al. (1973), serves to illustrate the origin of the temperature dependence (Figure 1).

Water evaporated from lower latitude oceans and continents is transported poleward as vapor. The vapor pressure of H_2^{16}O is slightly higher than that of H_2^{18}O (true also for H_2^{16}O versus HD^{16}O) and as a result vapor evaporated from seawater is depleted in the heavy isotope relative to the seawater source. Cooling of this vapor as it travels poleward causes condensation, removing water from the vapor phase. The condensed water is enriched in the heavy isotope (because the vapor pressure of water molecules containing the heavier isotope is lower than for water molecules containing the light isotope, slightly favoring condensation). The vapor parcel is thus progressively depleted in the heavier isotope as it moves toward the pole, and as a result $\delta^{18}\text{O}$ and δD values for polar snow and ice are highly negative. This is the underlying reason the oxygen isotope composition of the ocean varies with time – as the ice sheets grow they progressively remove isotopically depleted water from the ocean, leaving ocean water isotopically enriched. Because of the rather complex processes that lead to depletion of $\delta^{18}\text{O}$ and δD over the ice sheets these isotope

Figure 1 Schematic illustration of isotope fractionation ($\delta^{18}\text{O}$) from source in tropical ocean water to deposition site on an ice sheet. $\delta^{18}\text{O}$ of water vapor and precipitation is shown for summer and winter. Cooler winter temperatures lead to condensation and removal of a larger amount of water vapor during transport of moisture poleward, and a corresponding greater depletion of the heavy isotope in precipitation finally reaching the polar site. In an analogous way colder climates lead to greater isotopic depletion relative to warmer climates. The isotope values on this figure are primarily for heuristic purposes and the depiction neglects the temperature dependence of isotopic fractionation between liquid, vapor, and solid, which enhances the temperature dependence of isotope ratios at high (cold) latitudes (Cuffey and Brook, 2000). From Dansgaard et al. (1973).

ratios are not directly linked just to the surface temperature at an ice-core site. Instead, the simple picture outlined above suggests that $\delta^{18}\text{O}$ and δD are controlled by the temperature difference between the site and the moisture source. However, because temperature changes at high latitudes are generally larger than those at low latitudes a relationship between surface temperature and $\delta^{18}\text{O}$ and δD is expected (Patterson, 1994). The temperature dependence of isotopic fractionation is also important in controlling isotopic changes from source to ice-core site, and a simple mathematical description of the influence of both factors in a basic Rayleigh fractionation model is provided by Cuffey and Brook (2000). This simple picture is complicated by several factors which are discussed further below.

Measurements of $\delta^{18}\text{O}$ and δD in snow collected at various locations in Greenland and Antarctica validate this expectation and show a strong linear relationship with a slope of $\sim 0.6\text{--}0.7\text{‰}/^\circ\text{C}$ (Figure 2). δD values are generally $\sim 8 \times \delta^{18}\text{O}$; deviations from this relationship are caused by secondary processes that become important in interpreting isotope data and are discussed below. The figure of $0.6\text{--}0.7\text{‰}/^\circ\text{C}$ for oxygen isotopes is often called the 'spatial slope' to denote its origin in the spatial variation of isotope values at sites with different mean annual temperatures. The spatial slope has often been used as a calibrating isotopic thermometer and applied to ice-core records for reconstructing past temperature. This approach, substituting space for time in a climate reconstruction, is common in paleoclimatology, but as discussed below, is not entirely accurate for reconstructing temperature from ice cores.

Figure 2 Relationship between $\delta^{18}\text{O}$ of snow in Greenland and Antarctica and surface temperature. From Johnsen et al. (1989) and Dahe et al. (1994). Reproduced from Cuffey and Brook (2000).

One further issue regarding isotope records is relevant. Early work on stable isotopes in polar regions revealed large seasonal variations in the isotopic composition of snow but found that those variations were damped after deposition in the firn (snowpack). This is due to diffusion and redeposition of water vapor in the firn. Seasonal variations in $\delta^{18}\text{O}$ and δD are damped to the extent that at low deposition rate sites (e.g., deep ice-coring sites in Antarctica with accumulation rates $\sim 2\text{ cm/year}$) seasonal cycles in isotopic composition are not preserved. Even at high accumulation sites (e.g., deep drilling sites in Greenland with accumulation rates $>20\text{ cm/year}$) seasonal variations in isotope ratios are damped (Johnsen et al., 2000). Johnsen et al. traced the history of this problem and describe modeling with the goal of correcting isotope profiles for diffusion and reconstructing seasonal cycles. They also showed that diffusion in solid ice further smooths seasonal variations. Sampling ice cores at seasonal resolution is common for shallow cores covering the last few centuries and such studies must consider the impact of smoothing due to diffusion. Sampling of deeper cores generally averages over many seasonal cycles. Seasonality in isotope ratios is an important issue, however, because bias in isotope records can be created by changes in the timing and amount of precipitation throughout the year.

Reliability of the Isotope Thermometer

There are a variety of reasons to think that the scenario outlined in Figure 1 oversimplifies vapor transport to the extent that the reliability of calibration based on modern measurements (spatial slope) for paleotemperature reconstruction

can be questioned. Rather than depending on a single well-understood temperature-dependent isotopic equilibrium, like some paleothermometers, the isotopic composition of polar precipitation is dictated by the influence of processes at the moisture source, during transport, and at deposition. At the source, one problem is that the whole ocean water isotopic composition changes with time as the ice sheets wax and wane. This can be accounted for using isotope records from calcareous fossils ocean sediments as proxies for changing ocean isotopic composition (see Jouzel et al., 2003 and Kavanaugh and Cuffey, 2003 for recent discussion of correction techniques), but these contain a mixed signal of changes in water isotopic composition and the temperature dependence of isotope fractionation on the formation of CaCO_3 skeletons, creating some uncertainty in the corrections. Recent work on independent temperature estimates for the deep sea using Mg/Ca ratios will help in this regard.

A second problem at the source is that the location, and therefore possibly the temperature and isotopic composition, of the moisture source may change with time. This might arise due to changes in storm tracks (Charles et al., 1994) or other large-scale meteorological parameters. A third is that positively correlated changes in moisture source temperature and ice-core site temperature will damp inferred temperature changes from the ice-core isotope record. For example, Boyle (1997) suggested that a 5°C cooling of the tropics and subtropics during glacial times would change the apparent isotope-temperature sensitivity in such a way that the glacial-interglacial temperature change would be underestimated by using the spatial slope.

Complications also potentially arise during vapor transport. 'Recycling' of water vapor between the ocean and atmosphere complicates the simple picture of Figure 1, though the significance diminishes at high latitudes (Kavanaugh and Cuffey, 2003; Hendricks et al., 2000). Kinetic fractionation during snow formation in clouds, the possible influence of impurities, and other processes in clouds and precipitation have also been considered (Jouzel et al., 1997; Alley and Cuffey, 2000; Kavanaugh and Cuffey, 2003).

Site processes are also significant. First, seasonal and shorter-term meteorological variations at the ice-core site may be important (Cuffey and Brook, 2000). Seasonal temperature variations at high latitudes are very large, creating seasonal variations in the isotopic composition of snow. Shifts in the timing and amount of precipitation within the year could bias isotope records (Steig, 1994; Denton et al., 2005) as could shifts in the location of storm tracks. This topic has been discussed extensively for Greenland (for discussion see Denton et al., 2005), and may contribute to the discrepancy between spatial slope and isotope-temperature relationships derived from other methods (see below). For Antarctica the influence of changes in seasonality is thought to be of secondary importance (Jouzel et al., 2003). Finally, since snowfall rates are higher under warmer conditions in the polar regions the isotopic composition of snow may conceivably be biased toward shorter term events caused by the poleward advection of warm air (Cuffey and Brook, 2000).

Another site phenomenon to consider is the strength of the temperature inversion (warmer air aloft than at the surface) that can exist over an ice sheet. The isotopic composition of snowfall depends on the temperature where precipitation

forms in the atmosphere (Jouzel et al., 1997) rather than the ice-sheet surface temperature. A change in the strength of the inversion (e.g., between glacial and interglacial times) could bias the reconstruction of temperature from the isotope record. Krinner et al. (1997) examined this effect for Greenland in a global circulation model (GCM) study and found it to be relatively small.

Finally, deep ice-core isotope records are typically interpreted in terms of changes in temperature with respect to modern climate at the ice-core site (whether it be surface or air temperature aloft). The dynamics of ice flow can complicate this simple scenario, however. If ice in deeper sections of a core was deposited at higher altitudes than the core site (possible if the core is not drilled on an ice divide) the isotopic composition of that ice would reflect both differences in climate and the impact of elevation change (every 100 m change in elevation results in a $\sim 0.6^\circ\text{C}$ change in temperature). This problem is important for interpreting some well-known ice-core records, e.g., those from Camp Century and Dye 3 sites in Greenland, and to a lesser extent the Vostok and Byrd sites in Antarctica.

In light of the complications of the temperature dependence of isotope ratios in polar precipitation described above several studies have used more complex atmospheric models incorporating isotopes to examine the reliability of paleotemperature reconstructions using isotopes. In general, GCM studies that incorporate water isotopes have confirmed the temperature dependence of isotope ratios in high latitude snowfall (Jouzel et al., 1997; Delaygue et al., 2000; Werner et al., 2001; Kavanaugh and Cuffey, 2003) although such studies have also shown how the phenomena discussed above can influence the isotope ratio-temperature calibration and reveal spatial variations in the isotope ratio versus temperature relation. GCM studies for Antarctic precipitation generally confirm the validity of using the spatial slope for determining temporal temperature trends, though tend to suggest temporal slopes are slightly lower than spatial slopes (Jouzel et al., 2003). GCM and other modeling studies for Greenland tend to confirm other work (below) that indicates that the spatial slope is not an accurate calibration for determining temperature from Greenland ice cores (Hendricks et al., 2000; Krinner et al., 1997; Delaygue et al., 2000).

Independent Tests of the Isotope Thermometer

As a result of the problems raised in the previous section, a number of recent studies have attempted to test the application of the isotopic thermometer with independent temperature estimates. For example, in Greenland, Shuman et al. (1995) compared isotope ratios in snow pits at Summit Greenland with satellite-derived and direct measurements of temperature over several seasonal cycles. They obtained excellent agreement between temperature and isotopic trends. They inferred an isotope-temperature sensitivity of $\sim 0.4\text{--}0.5\text{‰}/^\circ\text{C}$, similar to, but slightly lower than, the spatial sensitivity. Groote and Stuiver (1997) compared surface temperature and the isotopic composition of newly fallen snow, frost, and water vapor. They found that water vapor had a sensitivity higher than the spatial slope, $0.83\text{‰}/^\circ\text{C}$, and suggested that water vapor exchange and other processes during vapor transport may have

influenced this result. Similar work in Antarctica is described in the chapter entitled 'Stable isotope records from Antarctic Ice Cores'.

Instrumental calibrations are useful but clearly cannot test the accuracy of the isotopic thermometer for large climate changes in the more distant past. Two independent approaches have provided such a test, but with very different temporal resolution. The first independent test of the isotope thermometer is derived from borehole temperature measurements. The temperature profile in an ice sheet is controlled by the surface temperature history, heat transfer in the ice, and geothermal heat flux. As described in the chapter entitled 'Borehole temperature records and inferences of temperature change', under appropriate conditions the modern temperature profile measured in a fluid-filled borehole can be inverted to reveal a temperature history. This temperature history is a smoothed version of the true temperature history due to heat transport in the ice. Nonetheless, temperature changes over a variety of timescales (Little Ice Age, Holocene, glacial–interglacial) are accessible from borehole records, although information for times prior to the last glacial period is not preserved. Cuffey et al. (1995) describe an explicit test of the isotope thermometer with borehole data from the Greenland Ice Sheet Project-2 (GISP2) ice core. They used an inverse method in which they assumed the temperature history was proportional to the relative variations in the GISP2 isotope record without employing the calibration between isotope ratios and temperature. This method suggests varying isotopic sensitivity for different time periods. The glacial–interglacial transition has a sensitivity of about $0.33\text{‰}/^{\circ}\text{C}$ (Cuffey et al., 1995), while the sensitivity to mid-late Holocene cooling was smaller, $0.25\text{‰}/^{\circ}\text{C}$. At the termination of the Little Ice Age the sensitivity was $0.5\text{‰}/^{\circ}\text{C}$. Similar results were obtained using slightly different methods for the Greenland Icecore Project (GRIP) borehole record (Dahl-Jensen et al., 1998).

An alternate test of the isotope thermometer is provided by records of the stable isotopic composition of nitrogen and argon in air bubbles in Greenland ice cores. In the firn layer of an ice sheet gases are mobile and subject to both gravitational settling and thermal diffusion. Thermal diffusion impacts the isotopic composition of these gases when a temperature gradient is created in the firn, for example during abrupt temperature changes in Greenland or during seasonal temperature changes (Severinghaus et al., 2001). The result is an isotopic anomaly in nitrogen and argon isotopes that both marks the time of abrupt warming in the gas record and can be used to reconstruct temperature change. In the late 1990s, Jeff Severinghaus showed that by measuring nitrogen and argon isotopes, which have the same sensitivity to gravitational fractionation but different thermal diffusion sensitivities, one could determine temperature change independent of the water isotope record, at least for abrupt events (Severinghaus et al., 1998; Severinghaus and Brook, 1999). In the original work on this subject Severinghaus et al. demonstrated the potential of the paired argon and nitrogen isotope data, but uncertainties were too large to allow highly accurate temperature change estimates. They were able to estimate temperature change at the end of the Younger Dryas using the data in an alternate way, however. Using the nitrogen isotope anomaly as a stratigraphic marker they were able to estimate the age

difference between gas bubbles and the surrounding ice by counting the number of annual layers between the gas anomaly and the onset of warming recorded in the ice isotope record. This offset is temperature dependent, and allowed them to estimate a temperature of -46°C for the Younger Dryas, approximately 7°C colder than the estimate based on the spatial slope, and close to the value inferred from the temporal slope derived from borehole temperatures (Severinghaus et al., 1998). In later work, Severinghaus and Brook (1999) were able to use nitrogen and argon isotope data for the warming at the onset of the Bølling period to reveal an abrupt warming of $9 \pm 3^{\circ}\text{C}$ and an isotope-temperature slope of $0.38\text{‰}/^{\circ}\text{C}$, again close to the borehole value. (Subsequent work based on updated diffusion parameters adjusted the temperature change to $11 \pm 3^{\circ}\text{C}$; Severinghaus et al., 2003.) Later work on other abrupt changes revealed variable sensitivities (Landais et al., 2004a, b; Lang et al., 1999) but all with isotope-temperature sensitivity lower than those derived from the spatial slope model.

In Antarctica, borehole temperature reconstructions and the firn gas thermometer are more difficult to apply due to damping by heat diffusion for the borehole temperature case and the lack of abrupt temperature changes and high accumulation rate sites for the latter. Salamatin et al. (1998) analyzed Vostok borehole temperatures and concluded that spatial slopes underestimate temperature changes based on δD . Significant uncertainties limit the accuracy of the results (Jouzel et al., 2003). Caillon et al. (2003) studied a rapid warming in the Vostok record at about 107–108 thousand years (ka) using the N and Ar isotope technique and concluded that the spatial slope underestimated temperature change by $\sim 20\%$ for that event.

In summary, calibration and tests of the isotopic thermometer support the notion that δD and $\delta^{18}\text{O}$ values for ice samples qualitatively reflect temperature change, but also indicate that the sensitivity of the isotope ratios to temperature may change with time, and that substitution of space for time is not an appropriate calibration technique without independent testing. The problems are more apparent in Greenland records, where a variety of evidence implies a potential sensitivity range as seen by different methods of a factor of two. In Antarctica, however, available information suggests only a $\pm 20\%$ variation in isotope-temperature sensitivity. The latter conclusion is most relevant to the cold high elevation sites in East Antarctica (Jouzel et al., 2003). A number of reasons have been proposed to explain why the spatial and temporal slopes do not match in Greenland. The likely explanations include changes in seasonality, cooling of the moisture source, and changes in temperature inversion strength (Alley and Cuffey, 2000).

Deuterium Excess

The relationship between δD and $\delta^{18}\text{O}$ in polar regions is highly linear with a slope of approximately eight (Cuffey and Brook, 2000). The intercept of this relationship is not zero, however, and this offset, which arises due to kinetic isotope fractionation at the moisture source and fractionation during vapor transport (Cuffey and Brook, 2000; Kavanaugh and Cuffey, 2003) depends on climatic properties of interest including source

temperature and humidity. As a result, ice-core geochemists have defined this as deuterium excess, or d , as $d = \delta D - 8 \cdot \delta^{18}O$, and use it to examine source-related processes, primarily variations in source temperature (see [Kavanaugh and Cuffey, 2003](#), for a detailed discussion) which are of central concern for evaluating ice-core isotope records. Determining d requires that δD and $\delta^{18}O$ are measured on the sample. Recent examples of the use of deuterium excess in interpreting ice-core records include reconstructing source water temperatures for East Antarctic (Stenni et al., 2003) and Greenland ice cores ([Masson-Delmotte et al., 2005](#)) and correcting isotopic temperature records for source temperature changes ([Cuffey and Vimeaux, 2001](#); [Masson-Delmotte et al., 2005](#)).

Ice-Core Isotopic Stratigraphy

In this section the major features of ice-core stable isotope records from Greenland and Antarctica are reviewed. The reader is referred to separate articles on Antarctic records, Greenland records, and various articles on other ice-core records for more details. In general, isotope records from both hemispheres show the well-known cycling between cold glacial and warm interglacial states. In common with marine and other sedimentary climate records over these time periods the records have a strong 100 000 year cyclicity ([EPICA Dome community members, 2004](#)), as well as variation on 20 000 and 40 000 year timescales linked to Milankovitch cycles, at least as far back as the oldest ice-core record (720 000 years from the EPICA Dome C Core).

Deep ice cores from Greenland provide a detailed picture of climate change over the last 110 000–120 000 years, covering the Holocene and the last glacial period. Ice from the end of the last interglacial period is present in the North GRIP core ([NGRIP members, 2004](#)) and possibly in other Greenland cores ([Johnsen et al., 2001](#)) and older ice also appears to be present, but disturbed by ice flow and no longer in stratigraphic order ([Chappellaz et al., 1997](#); [Landaï et al., 2003](#); [Suwa et al. in press](#)). The most striking aspect of the Greenland records are the large isotopic fluctuations during the Ice Age ([Figure 3](#)) often called Dansgaard-Oeschger events. As discussed above, firn gas thermometry verifies that these represent large temperature changes. The chapter entitled ‘Methane Studies’ discusses the relationship between the abrupt events in Greenland and millennial-scale climate change in Antarctica and the chapter entitled ‘SubMilankovitch (DO/Heinrich) events’ discusses the abrupt events in a broader context.

Antarctica provides longer records due to colder conditions and lower accumulation rates, and the oldest Antarctic record, from EPICA Dome C, is plotted in [Figure 4](#). This record extends to 720 000 years, and may be lengthened by further drilling and analysis. The dominant 100 000 year cycle is evident as well as shorter term Milankovitch cyclicity mentioned above. The similarity of the Antarctic δD record to the marine stable isotope record, which reflects global glacial–interglacial conditions, is readily apparent, reinforcing the conclusion that the Antarctic ice-core record is an appropriate indicator of long-term trends in global climate.

Figure 3 Stable isotope records for the last glacial period from Greenland (top) and Antarctica (bottom). GISP2 record from [Grootes et al. \(1993\)](#), NGRIP record from [NGRIP members \(2004\)](#), Byrd record from [Blunier and Brook \(2001\)](#).

¹⁰Be and Cosmogenic Radionuclides in Ice Cores

R Muscheler, Lund University, Lund, Sweden

© 2013 Elsevier B.V. All rights reserved.

Introduction

Studies of cosmogenic radionuclides in ice cores combine two distinct advantages. On the one hand, ice cores represent the most direct natural archive of climate change since they directly preserve past precipitation, its chemical and isotopic composition, and the ambient atmosphere. On the other, cosmogenic radionuclides represent a relatively simple system with a well-known production in the atmosphere and an even better-constrained sink–radioactive decay. Therefore, it is possible to reconstruct the production history and the geochemical behavior of cosmogenic radionuclides in great detail. Examples of this research include solar activity reconstructions, geomagnetic field reconstructions, dating/correlation of ice cores, and the study of atmospheric circulation and depositional processes.

There is a long list of cosmogenic radionuclides but only a few have suitable half-lives and concentrations to be of interest for ice-core studies. ¹⁰Be with a half-life of about 1 390 000 years (Chmeleff et al., 2010; Korschinek et al., 2010) is the most commonly measured cosmogenic radionuclide in ice cores. ³⁶Cl ($T_{1/2}$ = 301 000) is also often part of major ice-core drilling programs. These nuclides can be routinely measured in ice cores but their low concentrations usually lead to the requirement of large sample sizes (in the order of 100 g of ice) and sophisticated measurement techniques such as accelerator mass spectrometry (Litherland, 1980). Other cosmogenic radionuclides that have been measured in ice cores include ³H, ³²Si, ¹⁴C, ²⁶Al, and ⁸¹Kr (Lal and Jull, 1992, and references therein). In this article, the focus lies on cosmogenic radionuclides although the production of some of these nuclides by anthropogenic means (nuclear weapons and reactors, primarily) can be relevant (such as the bomb peak in ³⁶Cl). In the first section of this article, the processes influencing cosmogenic radionuclides from production to deposition in ice cores will be discussed. In the second section, some of the most important results of cosmogenic radionuclide studies in ice cores will be presented.

Cosmogenic Radionuclide Basics

Three factors influence cosmogenic radionuclides in ice cores: production, deposition, and postdepositional processes in the ice (Figure 1). The importance of these processes for the interpretation of radionuclides in ice cores is examined.

Production

Cosmogenic radionuclides, as the name indicates, are produced by the interaction of galactic cosmic rays (GCRs) with the atoms in the atmosphere and on the Earth's surface. High-energy cosmic rays originate in the galaxy and their origin is probably connected to supernova explosions. Different processes are responsible for modulation of the cosmic ray flux

reaching the Earth's atmosphere and, therefore, the varying cosmogenic radionuclide-production rates.

Solar modulation

GCRs mainly consist of charged particles. The nuclear component consists of 87% protons, 12% α -particles, and 1% heavier nuclei (Simpson, 1983). In the heliosphere, they interact with the solar magnetic field that is carried by the solar wind. The amount of GCRs reaching the Earth's atmosphere depends on the strength of the magnetic field and the energy of the GCR particles. Lower energy GCR particles get preferentially deflected with higher solar shielding (Lal and Peters, 1967). Low solar activity implies less solar magnetic shielding, more cosmic rays reaching the Earth, and higher production rates of cosmogenic radionuclides. Without going into the details it should be noted that the drift of the GCRs in the heliosphere also depends on the polarity of the solar magnetic field. For example, the well-known solar 11-year cycle is a 22-year polarity cycle as sunspots indicate strong magnetic fields on the Sun but not the polarity. However, for most applications, the so-called force-field approximation (Gleeson and Axford, 1968), where the solar modulation process can be described with one single parameter, the so-called solar modulation function, is sufficient. Low solar activity implies a low solar modulation function and higher fluxes of GCRs.

Geomagnetic modulation

A similar shielding effect occurs around the Earth due to the geomagnetic field. The higher the field intensity, the larger is the shielding and the fewer GCRs can enter the atmosphere. This process is strongly dependent on the geomagnetic latitude. No modulation occurs at the geomagnetic poles due to vertical magnetic field lines (parallel to the incoming GCRs), while there is a maximal shielding effect at the equator (e.g., Masarik and Beer, 1999). An absent geomagnetic field would lead to an increase in the radionuclide-production rates of about a factor of 2.

When high-energy GCRs enter the atmosphere, they produce a cascade of reactions (which produces the so-called secondary cosmic rays) and in some instances these produce cosmogenic radionuclides. Most cosmogenic radionuclides are produced via spallation reactions on heavier atmospheric particles (e.g., ¹⁶O = >¹⁰Be, Ar = >³⁶Cl, etc.). However, radiocarbon (¹⁴C) is mainly produced via capture of thermal (slow) neutrons by nitrogen. Due to the different production processes, the ¹⁰Be and ¹⁴C production rates react slightly differently to solar and geomagnetic field changes (Figure 2).

GCR variations

In most studies, it is assumed that the GCR flux was constant over the periods of interest in ice-core studies. From meteorite investigations and additional terrestrial evidence, it can be concluded that the GCR intensity has been constant within

10% during the past 10 million years (e.g., [Wielers et al., 2011](#)). In addition to the meteorite evidence, there is presently no need to invoke GCR variations as an explanation for ice-core cosmogenic radionuclide records. For example, one of the most prominent and reproducible ^{10}Be changes is an increase by about a factor of 2 about 40 000 years ago. In early studies, a GCR change was suggested as a potential (but unlikely) explanation ([Raisbeck et al., 1987](#)). Later on, it became clear that this event can be fully explained by a geomagnetic field minimum ([Baumgartner et al., 1998](#)).

Solar proton events

In general, solar cosmic rays, that is, particles ejected from the Sun, are not energy-rich enough to produce significant

amounts of cosmogenic radionuclides. Nevertheless, during solar proton events (SPEs), when the Sun emits a large amount of higher-energy particles, solar particles might produce detectable increases in radionuclide-production rates on short timescales. During such an event, the number of particles penetrating the atmosphere at the polar regions can be several orders of magnitude higher than the flux of GCRs ([Lal and Peters, 1967](#)). However, the energy of the solar particles is, on average, much lower than that of the GCRs. Therefore, the solar proton contribution to the radionuclide-production rates depends strongly on the energy thresholds for the production of the different radionuclides ([Lal and Peters, 1967](#)). For ^{10}Be , it has been suggested that SPEs contribute about 1–2% of the total average ^{10}Be -production rate ([Usoskin et al., 2006](#)). There are some studies that discuss the possibility of detectable SPEs in ice-core ^{10}Be records (e.g., [Pedro et al., 2009](#); [Usoskin et al., 2006](#)). However, the studies are rather vague on the reliability of the solar proton signal in the data as weather and climate ‘noise’ potentially masks the small effects due to SPEs. This is illustrated in a publication by [Pedro et al. \(2011\)](#), which shows that a ^{10}Be increase, that was previously suggested to be of SPE origin, did not stand out as a clear signal in an extended ^{10}Be record. The discussion concentrates on the GCR-related production processes and the results that can be drawn from them.

Figure 1 Illustration of the processes that are important for the interpretation of cosmogenic radionuclides in ice cores.

Transport and Deposition

The majority of the cosmogenic radionuclides are produced in the stratosphere (e.g., [Heikkilä et al., 2009a](#); [Masarik and Beer, 1999](#)). Therefore, the exchange processes between the stratosphere and troposphere influence the deposition rates

Figure 2 Globally averaged radionuclide-production rates according to [Masarik and Beer \(1999\)](#) depending on geomagnetic field intensity and solar-modulation function. The opaque surface shows the ^{10}Be -production rates and half-transparent ^{14}C -production rates.

of cosmogenic radionuclides. After the production, ^{10}Be attaches to aerosols (similar to ^7Be and ^{26}Al) and follows their pathways down to the Earth surface. ^{36}Cl , on the other hand, stays in a more gaseous form as HCl . ^{14}C oxidizes to CO_2 and enters the global carbon cycle. These differences influence the atmospheric lifetime, pathways, and deposition of the different cosmogenic radionuclides. ^{10}Be and ^7Be (similar to ^{36}Cl and ^{26}Al) are deposited within an average period of about 1 year (McHargue and Damon, 1991; Raisbeck et al., 1981a) while ^{14}C stays much longer (~ 5 years) in the atmosphere. The atmospheric pathways of ^{10}Be have been modeled with general circulation climate models (GCMs) (Field et al., 2006; Heikkilä et al., 2008a). The results show that the radionuclide-deposition rates depend on the precipitation rates and the preferred locations and season for the stratosphere–troposphere exchange in the mid-latitudes.

An important issue for polar ice-core records is whether they show a polar bias, that is, whether they deviate from the globally average production signal. As mentioned, there is a strong asymmetry of the cosmogenic radionuclide-production rates from the poles to the equator due to geomagnetic shielding. This effect also implies that the relative variations in cosmogenic radionuclide-production rates induced by a variable solar shielding are much larger at the poles than at the equator. Therefore, it has been suggested that this effect has to be taken into account when using ^{10}Be as a proxy for solar activity variations (Bard et al., 1997; Mazaud et al., 1994). GCM model results do not agree on this topic. While Field et al. (2006) see such a bias in their results, Heikkilä et al. (2009a) do not see such evidence in their higher resolution model. Comparison of ice-core ^{10}Be with ^{14}C data suggests a small polar bias, but the picture is not conclusive as this possible bias is not constant through time (Muscheler and Heikkilä, 2011).

There is ample evidence that the snow-accumulation rates have a strong effect on the ^{10}Be concentrations. The higher the accumulation rates, the lower the ^{10}Be concentrations. This applies to ^{10}Be deposition in space (e.g., differences between different locations; Delaygue and Bard, 2010) and in time (differences between different climate states; Wagner et al., 2001b). Alley et al. (1995) proposed separating the ^{10}Be signal into two components, where component I could best be explained with ‘wet deposition.’ For wet deposition one does not expect that the ^{10}Be concentrations depend on the snow-accumulation rates (more snow would imply proportionally more ^{10}Be deposition). Component II can be described as ‘dry deposition’ where additional snowfall would directly dilute the ^{10}Be signal and lead to lower ^{10}Be concentrations. In reality, the majority of the ^{10}Be is deposited with precipitation, with the exceptions of very low accumulation sites (Heikkilä et al., 2008a), but the wet deposition might indeed have a signature that is typical for dry deposition. For example, if atmospheric ^{10}Be gets depleted during the course of a precipitation event, the ^{10}Be concentration in the ice would depend on the precipitation rate. Another process that has to be considered at some locations is the input of ‘recycled’ cosmogenic radionuclides attached to dust. A nearby dust source could increase the input of cosmogenic radionuclides considerably and, therefore, perturb the signal if one is interested in the direct meteoric input of cosmogenic radionuclides. This problem is likely to be relevant for ice cores that are close to areas

that are significant sources for dust. In the center of the two large polar ice sheets, this effect is considered to be of minor importance (Baumgartner et al., 1997).

Postdepositional Processes

The most obvious process relevant for radionuclides in ice cores is radioactive decay. Depending on the half-life, it leads to a depletion of cosmogenic radionuclides with age. However, ice-core radionuclide studies are usually done with radionuclides that have a ‘suitable’ half-life, that is, such studies are usually focused on ^{10}Be and sometimes also on ^{26}Al and ^{36}Cl but hardly on shorter-lived radionuclides such as ^7Be . Nevertheless, there are other processes in the ice that might alter the radionuclide concentrations or the availability of the radionuclides for measurements.

Dust-borne ^{10}Be

Dust-borne (recycled) ^{10}Be is usually a factor that one wishes to exclude when interpreting polar ice-core records in terms of production-rate changes. This component can be separated by filtering the meltwater before sample preparation. However, measurements of ^{10}Be in meltwater and on filters indicate that the older the ice, the more ^{10}Be can be found on the dust (Baumgartner et al., 1997). The process is not satisfactorily understood, but the data could be explained with a time-dependent process that leads to an attachment of ^{10}Be to the dust grains (that are removed by filtering the meltwater through a fine-meshed filter). Processes within the ice matrix, such as recrystallization, might be responsible for the transport of ^{10}Be to the crystal borders where it attaches to the dust. However, an expected correlation with dust amount cannot be found. Similarly, Raisbeck et al. (2006) find large spikes in ^{10}Be concentrations in very old ice from the European Project for Ice Coring in Antarctica (EPICA) ice core drilled at DomeC (East Antarctic Plateau) that cannot always be confirmed by remeasuring ice of the same depth/age. This could indicate that, by coincidence, one can sample ice with dust that accumulated ^{10}Be and leads to considerable ^{10}Be increases. However, ice from the same depth does not necessarily contain the same amount of dust and ^{10}Be attached to it and some samples might be depleted of ^{10}Be .

^{36}Cl mobility

In contrast to ^{10}Be , ^{36}Cl stays in a gaseous phase in the form of HCl . Mobility of HCl in the firm could lead to a smoothening of the ^{36}Cl signal and a loss of ^{36}Cl back to the atmosphere. Based on the bomb- ^{36}Cl peak profile, it has been shown that radionuclide concentrations can, after their deposition, be altered by exchange processes within the firm. Delmas et al. (2004) investigated the ^{36}Cl bomb signal in the firm at the Vostok Station in central East Antarctica. The profile suggests that HCl is mobile in firm and that diffusion processes can alter the atmospheric input signal in the ice. This may seriously question the usefulness of the $^{10}\text{Be}/^{36}\text{Cl}$ dating method but this process is likely to be less important when accumulation rates are higher and the acidity of the ice is low (e.g., during ice-age conditions; Delmas et al., 2004).

In situ production

In situ production of cosmogenic radionuclides in the ice has been shown to be a significant process for ^{14}C (Fireman and Norris, 1982; Lal et al., 1990). This means that the cosmic ray flux at the top of an ice sheet can produce cosmogenic radionuclides in measurable amounts in the uppermost layers of the ice sheet. ^{14}C is produced via spallation reactions on the oxygen in the ice. Even below ~ 10 m, there could be a significant production of ^{14}C due to the muons in the GCR shower (Van Der Kemp et al., 2002). The *in situ* contribution is often considered negligible for ice-core ^{10}Be studies due to the relatively large amounts of meteoric ^{10}Be . However, especially at low accumulation sites, this process could add a ^{10}Be signal that cannot be neglected (Horiuchi et al., 2008).

Applications

In spite of the uncertainties in our knowledge regarding the production, transport, and deposition processes, there is a wealth of information that can be gained from ice-core radionuclide records. Some of the most important applications and results are presented here.

Solar Activity Reconstructions

The solar modulation of the GCR flux to the Earth's atmosphere leads to a solar signal in the radionuclide-production rates. Especially, ^{10}Be records have been used to reconstruct the history of the Sun. Beer et al. (1990) were the first to trace the solar 11-year cycle with high-resolution ^{10}Be measurements in an ice core from Southern Greenland. Major solar minima, such as the Maunder Minimum from about AD 1645 to 1715, are usually clearly visible also in lower resolution ^{10}Be data. Figure 3 shows a compilation of ice-core ^{10}Be records for the last 1000 years. The data show a common signal that can be attributed to a series of solar minima (Oort (AD ~ 1020 –1070), Wolf (AD ~ 1270 –1340), Spörer (AD ~ 1400 –1540), Maunder (AD ~ 1615 –1715), and Dalton (AD ~ 1800 –1830)), but there are also differences when it comes to the amplitude and timing in the different records. The differences can most likely be attributed to (1) climate and weather influences on the ^{10}Be transport and deposition, (2) measurement quality issues, and (3) dating uncertainties. Such unresolved uncertainties are usually not a problem for qualitative solar activity reconstructions, but they can lead to important differences when such records are used to provide a solar forcing record for the past. This is best illustrated by two widely different conclusions about past changes in solar activity. Bard et al. (2000) conclude that solar activity was similar to present levels around AD 1200, while Usoskin et al. (2003) suggest that solar activity reached a maximum in the second part of the twentieth century that was significantly higher than during the preceding 1000 years. The main difference is the underlying ^{10}Be data set that the authors based their conclusions on. The ^{10}Be record from the South Pole, which Bard et al. (2000) include in their analysis (Figure 3(c)), does not show a similarly strong decreasing trend during the twentieth century compared to the ^{10}Be record from Southern Greenland (Figure 3(e)), which Usoskin

Figure 3 Several published ^{10}Be records for the last 1000 years from Greenland and Antarctica (Beer et al., 1988; Beer et al., 1990; Beer et al., 1991a; Berggren et al., 2009; Horiuchi et al., 2008; Muscheler et al., 2004; Raisbeck et al., 1990; Yiou et al., 1997) together with the group sunspot record (Hoyt and Schatten, 1998). Major solar minima are highlighted with the gray shading. Dots indicate noncontinuous measurements.

et al. (2003) prefer in their analysis (Muscheler et al., 2007; Raisbeck and Yiou, 2004). It is obvious that the implications for the inferred sun–climate link are very different depending on the solar-forcing reconstruction.

Going further back in time, there is one published high-resolution ^{10}Be record for approximately the last 9300 years (Muscheler et al., 2004; Vonmoos et al., 2006; see Figure 4). The ^{10}Be variations agree relatively well with the changes in the atmospheric ^{14}C levels as reconstructed from tree-ring ^{14}C measurements (Vonmoos et al., 2006). This implies that the major Maunder and Spörer Minimum-type solar minima can be reliably seen in ice-core ^{10}Be records over millennia back in time. However, the absolute levels of solar activity remain uncertain mainly because of differences between the different radionuclide records and uncertainties in the necessary geomagnetic field correction (Vonmoos et al., 2006).

The problem of disentangling the solar signal from ice-core ^{10}Be records gets even more challenging if one goes further back in time. The deglaciation and the end of the last Ice Age (about 11 600 years ago) implied changes in the atmospheric circulation and snow-deposition rates. The consequences for the ^{10}Be deposition are unclear. A simple subtraction of the geomagnetic influence on the GRIP ice-core ^{10}Be record would suggest high solar activity levels during the last Ice Age since the ^{10}Be data are lower than expected from the geomagnetic field data (Muscheler et al., 2004). However, without a better

Figure 4 ^{10}Be concentration (panel (b)) and fluxes (panel (c)) from the GRIP and GISP2 ice cores from Central Greenland (Finkel and Nishiizumi, 1997; Muscheler et al., 2004; Vonmoos et al., 2006; Yiou et al., 1997) together with the GRIP $\delta^{18}\text{O}$ record (Johnsen et al., 1997) (panel (a)). The Dansgaard/Oeschger events during the last Ice Age imply accumulation-rate changes in the order of a factor of 2.

knowledge of the climate influence on the ^{10}Be deposition, such a conclusion cannot be drawn. Nevertheless, it is possible to concentrate on known solar changes even during periods of a highly varying climate. With this approach, it is possible to extract a limited but more reliable solar signal. Wagner et al. (2001c) found the solar 207-year cycle, which clearly stands out in the Holocene radionuclide records (Suess, 1982), in the ^{10}Be data from the GRIP ice core from 50 000 to 25 000 years before present supporting the solar origin for part of the ^{10}Be variability in the glacial section of this deep ice core from Central Greenland.

Geomagnetic Field Reconstructions

One of the most prominent features of ice-core ^{10}Be records is a doubling of the ^{10}Be concentration dating to about 40 000 years ago (Figure 4). Possible explanations were a climate influence, snow-accumulation rate changes, changes in primary cosmic ray intensity (e.g., due to a nearby supernova explosion), a geomagnetic field intensity minimum or low solar activity (Raisbeck et al., 1981b; Raisbeck et al., 1987). With improved data and better timescales, it could be shown that timing and amplitude of the radionuclide peak fit with the so-called Lascamp geomagnetic field minimum (Baumgartner

et al., 1998). In addition, for the last 60 000 years, there is a generally good agreement between independent geomagnetic field reconstructions and cosmogenic radionuclide fluxes to the GRIP ice core in Central Greenland (Muscheler et al., 2005; Wagner et al., 2000). Furthermore, Raisbeck et al. (2006) found the ^{10}Be signature of the last geomagnetic field reversal about 800 000 years in ice from the DomeC ice core.

From the ^{10}Be records from Central Greenland it appears that the geomagnetic modulation is the dominant process for controlling the cosmogenic radionuclide flux on timescales of 3000 years and longer. However, it is difficult to draw the line where solar modulation might be less important and where the geomagnetic modulation becomes dominant. Such investigations depend strongly on the quality of the independent geomagnetic field reconstructions. By comparing ice-core ^{10}Be records with independent geomagnetic field reconstructions, one can infer that the geomagnetic shielding cannot be neglected on timescales of 500 years and longer (Snowball and Muscheler, 2007).

^{14}C and Ice Cores – *In Situ* Production and Dating

^{14}C is the most important tool to date geological archives for the last 50 000 years. However, ^{14}C dating of polar ice cores is difficult as ^{14}C in air trapped in ice cores shows not only the atmospheric signal but is also strongly influenced by *in situ* production of ^{14}C in the snow and firn, mainly via interaction of secondary cosmic rays with oxygen (Lal et al., 2005; Wilson and Donahue, 1992) and via interactions of muons with oxygen (Nesterenok and Naidenov, 2011). The *in situ* production depends on snow-accumulation rates (i.e., how quickly the snow and firn get shielded) and cosmic ray intensity (geographic latitude, height, and solar activity). The additional *in situ* signal can dominate the measured ^{14}C concentrations.

Lal et al. (2005 and references therein) estimated the solar shielding based on the *in situ* ^{14}C signal in the GISP2 ice core. This method has the potential to add valuable information about long-term changes in solar activity. However, several processes complicate the interpretation. These consist of accumulation-rate changes that influence the shielding (Lal et al., 2005), variations in the local cosmic ray flux that are not related to solar activity (e.g., elevation changes; Lal et al., 2005), separation of the *in situ* and atmospheric signal, input of dust-borne carbon, and loss of ^{14}C from the firn (Smith et al., 2000). Nevertheless, Lal et al. (2005) conclude that it is possible to pinpoint periods of elevated and lower solar activity with this method.

^{14}C in low-latitude ice cores, where input from terrestrial carbon sources is more abundant, has been successfully used to date the ice (Jenk et al., 2009; Sigl et al., 2009).

Dating and Correlation

As mentioned, ^{14}C dating is possible in ice cores from low latitudes, but for polar ice-cores cosmogenic radionuclides provide additional possibilities to date the ice.

On the one hand, the radionuclide concentrations are negatively correlated to accumulation-rate changes and, therefore, allow us to estimate changes in accumulation rates (Wagner et al., 2001b) that then are a key parameter for age modeling.

On the other, the globally synchronous variations in the radionuclide-production rates allow us to synchronize different environmental archives that have detectable cosmogenic radionuclide variations due to solar or geomagnetic field variability (e.g., Finkel and Nishiizumi, 1997; Muscheler et al., 2000; Raisbeck et al., 2007; Yiou et al., 1997).

Finally, the radioactive decay of ^{10}Be and ^{36}Cl can be used to estimate the age of the lowermost/oldest ice of ice cores (Willerslev et al., 2007). The climate/accumulation rate influence on radionuclide records makes it difficult to use single radionuclide records for dating. However, it is possible to improve this method by analyzing radionuclide ratios under the assumption that climate influences have a similar impact on the radionuclides. The different half-lives of ^{36}Cl (301 000 years) and ^{10}Be (approx. 1 390 000 years (Chmeleff et al., 2010; Korschinek et al., 2010)) then lead to a time-dependent change in the $^{10}\text{Be}/^{36}\text{Cl}$ ratio ($^{10}\text{Be}/^{36}\text{Cl}$ half-life' = 384 000 years). With this approach, it was possible to constrain the age of the lowermost ice in the GRIP ice core to much older values than previously thought (Willerslev et al., 2007).

Accumulation-Rate Reconstructions

The influence of the variable-accumulation rate on radionuclide concentrations is a matter of current debate. The concept of separating the signal in a dry and wet deposition component was presented in the section 'Transport and Deposition.' For the GRIP ice core, the ^{10}Be concentration indicates that the signal can almost completely be explained by 'dry deposition.' For example, an accumulation-rate increase of a factor of two leads to roughly a halved ^{10}Be concentration (Figure 4). However, this effect is rather caused by an atmospheric depletion of ^{10}Be during periods of increased precipitation rather than by a real dry deposition process. Based on the varying ^{10}Be concentrations and known ^{10}Be production variations, Wagner et al. (2001b) estimated changes in past accumulation rates in Central Greenland during the strong climate fluctuations of the last Ice Age. This radionuclide-based estimate agrees well with layer thickness-inferred reconstructions of the snow-accumulation rate (Johnsen et al., 1995; Svensson et al., 2006; Wagner et al., 2001b).

Sun/Cosmic Ray–Climate Relation

The relation between solar activity changes and climate is a controversially discussed topic in climate change. Cosmogenic radionuclide records from ice cores have the advantage that solar/cosmic ray proxy data and climate data can be inferred from the same geological archive with virtually no errors in the relative dating. There are some examples where a solar influence on climate has been inferred from ice cores for the Holocene period (e.g., Grootes and Stuiver, 1997; O'Brien et al., 1995). However, the comparison of radionuclide and climate data for selected events suggests a complex relation between solar activity and climate change at the beginning of the Holocene (Björck et al., 2001). Furthermore, the hypothesis of a cosmic ray influence on climate can be tested with ice-core radionuclide and climate data. The doubling of the cosmic ray intensity during the geomagnetic field minimum around 40 000 years BP had no discernable effect on climate (Wagner et al., 2001a).

Atmospheric Circulation/Deposition

Atmospheric transport and deposition changes and their influence on cosmogenic radionuclides complicate the interpretation of these records in terms of production-rate changes. However, the major source region in the stratosphere and the deposition processes can provide complementary information about past circulation and climate changes and, therefore, be the subject of research in itself.

There are several studies where high-resolution (subannual) ^{10}Be records are presented and interpreted in terms of a combined signal of atmospheric circulation, stratosphere–troposphere exchange, and production. Pedro et al. (2011), for example, discuss several monthly resolution ^{10}Be records from Law Dome in East Antarctica. Besides the solar signal, there is a strong atmospheric signal probably related to a maximum stratosphere–troposphere exchange during the Southern Hemisphere late summer to early autumn. Beer et al. (1991b) report a bimodal (spring and fall) enhancement of ^{10}Be deposition during the year in Greenland. They suggest that both might be caused due to injection of stratospheric air. The autumn peak was proposed to be due to delayed transport of ^{10}Be from low to high Northern latitudes. Heikkilä et al. (2008b) discuss high-resolution data from a snow pit in Central Greenland and compare it to model results. They see maximum ^{10}Be concentrations during boreal summer. The differences highlight the fact that the atmospheric transport and weather/climate influences are still one of the biggest uncertainties in interpreting radionuclide records quantitatively.

The atmospheric transport can be studied with another cosmogenic radionuclide with a strong anthropogenic signal caused by the atmospheric nuclear weapon tests in the 1950s and early 1960s. These introduced comparably large amounts of ^{36}Cl into the atmosphere, visible as an increase by about a factor of 1000 in some archives (Heikkilä et al., 2009b). Combined model-data studies help to constrain the atmospheric ^{36}Cl input and test model performances with respect to transport and deposition of cosmogenic radionuclides.

Results from Low-Latitude Ice Cores

In general, low-latitude radionuclide ice-core records are more complicated to interpret. For example, the topography in mountainous areas leads to a more variable microclimate than on the large ice sheets on Greenland and Antarctica. In addition, low-latitude ice cores are closer to radionuclide sources other than the atmospheric production. For example, recycled ^{10}Be on dust cannot be neglected in Alpine ice cores. Radionuclide data from low latitudes has mainly been used for dating. This includes bomb-peak dating using ^{36}Cl or ^{137}Cs (Green et al., 2000; Thompson et al., 2002) or the ^{14}C dating of carbon from terrestrial sources mentioned earlier (Jenk et al., 2009; Thompson et al., 2005).

Conclusion

Radionuclide measurements in ice cores allow us to trace a variety of different natural and human-induced processes. These range from emission of anthropogenic sources of

radioactivity to dating of ice cores. An important field is the reconstruction of the solar and geomagnetic history over the past millennia and the relationship to climate change. Climate influences on radionuclide transport and deposition can complement climate reconstructions from independent natural tracers. The globally synchronous production-rate changes provide numerous marker horizons that allow us to correlate natural archives (e.g., ¹⁰Be in ice cores and ¹⁴C in tree rings). The low abundance of natural radionuclides in ice cores makes the measurements expensive and ice consuming. However, the wealth of information that can be gained from such records made radionuclide studies an integral part of the major deep drilling projects in polar areas.

Studies of Firn Air

C Buizert, Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark

Introduction

Firn is the intermediate stage between snow and glacial ice, which constitutes the upper 40–120 m of the accumulation zone of ice sheets. Within the firn a vast network of interconnected pores exists, which exchanges air with the overlying atmosphere. At the bottom of the firn column, air is permanently trapped within the ice matrix, storing an atmospheric sample from the time of pore closure. In this way, air bubbles in glacial ice have been used to reconstruct changes in atmospheric composition up to 800 ka back in time (Louergue et al., 2008; Lüthi et al., 2008; Petit et al., 1999).

If one thinks of glacial ice as a flask for storing samples of ancient atmosphere, then the firn is the valve that gradually closes the flask. But far from an ideal valve, the firn alters the composition of air as it travels downward, through, for example, gravitational separation (Craig et al., 1988; Schwander, 1989), diffusive smoothing (Spahni et al., 2003), and thermal fractionation (Severinghaus et al., 2001). An understanding of firn air transport processes is therefore essential for interpretation of ice core gas records. Continued exchange with the atmosphere furthermore keeps firn air at the firn–ice transition younger than the surrounding ice, resulting in an age difference (Δ age) between glacial ice and the air bubbles it contains (Schwander and Stauffer, 1984).

The firn itself also acts as an archive of old air, preserving a continuous record of atmospheric composition up to a century back in time (Kaspers et al., 2004). Sampling of firn air allows reconstruction of the recent atmospheric history of many trace gas species and their isotopic composition.

Firn Air Sampling

Firn Air Sampling Device

The primary means of studying firn transport is by sampling of firn air (Schwander et al., 1993). The principle is illustrated in Figure 1(a). The firn air sampling device (FASD) is lowered into a borehole drilled to the desired sampling depth. By inflating the bladder, firn air is isolated from the overlying atmosphere. The borehole is then purged from contamination by pumping on the purge and sampling lines. CO₂-mixing ratios are typically monitored on the air flow to assess whether the hole has been sufficiently purged. A baffle plate (Figure 1(b)) is often used to separate the purge and sampling lines. The purge flow has a higher risk of being contaminated by air leaking past the bladder, and is discarded. Air from the sampling line is normally collected in flasks, which are shipped to the laboratory for analysis. Field deployment of FASD and ice drill is shown in Figure 2.

In the deep firn, density layering causes air to flow preferentially in the horizontal plane during sampling. Sturrock et al. (2002) observed that the mixing ratios of CH₄, CO₂, N₂O, H₂,

and CO do not change systematically with time or air volume extracted during sampling at each level. They interpret this as evidence that the air from each sampling depth originates from a narrow horizontal firn layer, rather than from regions significantly above or below the FASD inlet. In shallow strata with higher permeability, the collection region is presumably closer to a sphere or ellipsoid.

At several sites, air sampled from the deepest firn strata was found to be slightly depleted in heavy gases and isotopologues such as δ Kr/N₂, δ Xe/N₂, δ^{15} N₂, and δ^{40} Ar (Severinghaus and Battle, 2006). The authors interpret this as a mass-dependent collection artifact caused by the large pressure gradients that the sampling procedure induces in these low-permeability layers.

Overview of Firn Sampling Sites

Firn air has been sampled from sites on both hemispheres, covering a wide range of climatic conditions. Table 1 gives an overview of sampling sites. The Law Dome DE08-2 site is characterized by a very high accumulation rate, which allows for reconstructing atmospheric variations with high temporal resolution. At sites on the Antarctic plateau (Dome C, Dome Fuji, Megadunes, Vostok), on the other hand, the oldest air can be found.

Physical Firn Structure and Transport Properties

Firn Density and Porosity

Polar firn is a porous medium that is densified gradually under the weight of overlying precipitation, until its density ρ approaches the pure ice density ρ_{ice} of around 920 kg m⁻³. The interstitial space between ice crystals is referred to as the porosity s , which is defined as the volume fraction not occupied by ice, or $s = 1 - \rho/\rho_{\text{ice}}$. It can be divided into open (s_{op}) and closed (s_{cl}) porosity; the former refers to pores that are still connected to the overlying atmosphere, whereas the latter refers to pores that have already been closed-off. Owing to firn densification, the porosity decreases with depth and air is gradually occluded in bubbles. At Siple station, Schwander and Stauffer (1984) found that 80% of the bubble volume is formed in the density range $795 < \rho < 830$ kg m⁻³. The average density $\bar{\rho}_{\text{co}}$ at which the bubbles are closed-off is found in this interval. This mean close-off density was found to be independent of accumulation rate, and is mostly a function of the site temperature (Martinier et al., 1992, 1994):

$$\bar{\rho}_{\text{co}} = \left(\frac{1}{\rho_{\text{ice}}} + 6.95 \times 10^{-7} T - 4.3 \times 10^{-5} \right)^{-1} \quad [1]$$

where T is the mean annual site temperature in K. The mean close-off density in eqn [1] was determined by total air content measurements in mature ice. It is defined through the porosity,

Figure 1 (a) The principle of firm air sampling (not to scale). The FASD is suspended in the borehole from a steel cable. (b) Sampling head of the University of Bern FASD. Photograph courtesy of Jakob Schwander.

which, at the atmospheric pressure of the site, matches the measured air content. Apart from temperature, the close-off density (and thereby the total air content) is also influenced by wind strength (Martinerie et al., 1994) and insolation (Raynaud et al., 2007).

A second useful definition is the full close-off depth z_{cod} (with corresponding ρ_{cod}), which is the depth where all air is occluded ($s_{\text{op}}=0$). The full close-off is deeper than the mean close-off depth of eqn [1]. The deepest point at which firm air can be sampled in the field is just above z_{cod} .

Several s_{cl} parameterizations exist. Schwander (1989) gives the following empirical relation based on measurements of bubble volume in ice samples from Siple station, Antarctica:

$$s_{\text{cl}} = \begin{cases} s \exp[75(\rho/\rho_{\text{cod}} - 1)] & \text{for } \rho \leq \rho_{\text{cod}} \\ s & \text{for } \rho > \rho_{\text{cod}} \end{cases} \quad [2]$$

It must be noted that measurements of bubble volume tend to underestimate closed porosity, as pores can be reopened by sample cutting. Severinghaus and Battle (2006) adapted eqn [2] for Summit, Greenland, to have a more gradual close-off.

An alternative parameterization is given by Goujon et al. (2003), based on density and total air content measurements from three Greenland and Antarctic sites:

$$s_{\text{cl}} = 0.37s \left(\frac{s}{\bar{s}_{\text{co}}} \right)^{-7.6} \quad [3]$$

where $\bar{s}_{\text{co}}$ is the mean close-off porosity $\bar{s}_{\text{co}} = 1 - \rho_{\text{co}}/\rho_{\text{ice}}$. Equation [3] is designed to be consistent with eqn [1] and indicates that 37% of the porosity is closed for $\bar{\rho}_{\text{co}}$. Both parameterizations are shown in Figure 3(a).

Open Porosity Air Flow and Transport Properties

In the firm–ice transition, air bubbles are trapped and advected downward with the ice. Conservation of mass demands airflow in the open pores to replace the air thus removed. Assuming the firm to be in steady state with respect to accumulation and densification, the downward velocity of air in the open pores can be derived from the porosity ratio and mass conservation (Buizert et al., 2012):

$$w_{\text{air}} = \frac{A\rho_{\text{ice}}}{s_{\text{op}}^*P_0} \left(\frac{s_{\text{cl}}(z_{\text{COD}})P_{\text{cl}}(z_{\text{COD}})}{\rho_{\text{COD}}} - \frac{s_{\text{cl}}(z)P_{\text{cl}}(z)}{\rho(z)} \right) \quad [4]$$

where A is the accumulation rate in m year^{-1} ice equivalent, $s_{\text{op}}^* = s_{\text{op}} \exp(M_{\text{air}}gz/RT)$, is the effective open porosity, P_0 the barometric pressure, $P_{\text{cl}}(z)$ the enhanced pressure in closed bubbles due to firm compaction, M_{air} the molar mass of air in kg mol^{-1} , g the gravitational acceleration, and R the molar gas constant. The result is plotted in Figure 3(b), together with the downward velocity of the ice layers $w_{\text{ice}} = A\rho_{\text{ice}}/\rho$. The ice layers descend faster than the air does, that is, the air in the open porosity is moving upward relative to the ice matrix. This back flow is due to compression of open pores by the firm densification process (Rommelaere et al., 1997).

Pore geometry and connectivity dictate the firm air transport properties. Gas diffusivity and permeability in firm samples

have been determined using direct measurements (Albert et al., 2000; Fabre et al., 2000; Schwander et al., 1988) and by modeling of gas transport in reconstructed pore geometries (Courville et al., 2011; Freitag et al., 2002). However, gas diffusivities determined on individual firn samples do not represent the transport properties of the firn as a whole (Fabre et al., 2000), showing that the lateral dimensions of the diffusive path exceed that of a typical firn core sample.

Density Layering

Polar firn is a layered medium that exhibits large density variations around the mean caused by seasonal changes in climatic conditions and precipitation density, as well as wind and insolation features that are preserved in the densification process. As high-density layers reach the close-off density first, they can form impermeable layers that inhibit vertical gas transport (Martinerie et al., 1992). Such sealing layers are often invoked to explain the presence of a non-diffusive zone, or lock-in zone

(LIZ) just above the bubble close-off depth (Battle et al., 1996; Landais et al., 2006). Firn air can be pumped from the LIZ, meaning a large (laterally) connected open porosity still exists in the low-density layers.

The high-density sealing layers have been linked to winter precipitation through measurements of water stable isotopes (Martinerie et al., 1992). Recent studies of firn microstructure indicate a density cross-over at $\rho \sim 600\text{--}650\text{ kg m}^{-3}$, suggesting that high density LIZ layers originate as low density layers at the surface (Freitag et al., 2004). Boreholes separated by as little as 65 m were found to have different firn air transport properties caused by lateral variability in the firn stratigraphy (Buizert et al., 2012).

Although the dense layers impede vertical transport, they do not completely seal off the air below. The air content implied by such fully sealing layers is incompatible with measurements in mature ice. Furthermore, at many sites, firn air transport models require finite gas diffusivity in the LIZ to reproduce the measured mixing ratios of trace gases

Figure 3 Firn characteristics at NEEM. (a) Firn density and porosity using the parameterizations of Schwander (1989) (solid line) and Goujon et al. (2003) (dashed line). (Severinghaus et al., 2010; Witrant et al., 2011). The back flow of air due to pore compression can be facilitated by (micro) cracks and channels in the dense layers.

Trace Gas Transport in the Firn

Zonal Description of Transport

The firn column is commonly divided into three zones, based on the gravitational isotopic enrichment of molecular nitrogen with depth (Sowers et al., 1992). The zones correspond to different modes of firn air transport, as depicted in Figure 3(c). The convective zone (CZ) refers to the upper few meters of the firn column, which are vigorously ventilated. The air in the CZ is essentially of current atmospheric composition, and consequently it has the same $\delta^{15}\text{N}_2$ as the atmosphere (which is zero by definition). Below the CZ we find the diffusive zone (DZ), where mass transfer is dominated by molecular diffusion. In diffusive equilibrium, gravitational separation gives enrichment in heavy isotopes with depth, as is evident from the presented $\delta^{15}\text{N}_2$ measurements. The lock-in depth is defined as the depth at which gravitational enrichment stops. Continued pore compaction leads to a decreasing effective diffusivity with depth; the lock-in depth corresponds to the point where diffusivity becomes effectively zero. At this depth the air gets isolated from the atmosphere, and therefore the lock-in depth determines the Δ_{age} in mature ice. Below the lock-in depth, we find the LIZ or non-diffusive zone, where advection with the ice matrix dominates the transport. Since advection does not discriminate between isotopologues, gravitational separation does not occur in the LIZ. The existence of the LIZ has been linked to the formation of high density sealing layers that inhibit vertical diffusion (see Section ‘Density Layering’).

Overview of Mass Transfer Mechanisms

Diffusion

Spatial variations in gas concentration or partial pressure lead to isobaric mass transfer along the gradient, from regions of higher to lower concentration. In porous media, such as polar firn or unsaturated soil, two types of diffusion should be considered. Knudsen diffusion occurs when the pore diameter is sufficiently small, or pressure sufficiently low, and molecules collide predominately with the walls rather than with other gas molecules. The second type is molecular diffusion, which represents the opposite regime of predominantly intermolecular collisions. In polar firn, the molecular free mean path of $\lambda \sim 100$ nm is about four orders of magnitude smaller than typical pore sizes of ~ 1 mm (Freitag et al., 2004; Kipfstuhl et al., 2009). Consequently, firn air diffusion is of the molecular type. In soils, particle and pore sizes are generally much smaller and Knudsen diffusion cannot always be neglected. Fick’s law is commonly used to describe molecular diffusion in firn. The validity of this approach has been questioned in the case of soil diffusion (Thorstenson and Pollock, 1989), in particular for studies of soil respiration (Freijer and Leffelaar, 1996). When modeling trace gas transport, Fick’s law provides a good approximation; it is not suited to describe transport of main components of air such as O_2 .

The effective diffusivity of gas X in the open porosity is given by (Dullien, 1975):

$$D_X = s_{op} \frac{D_X^0}{\tau} = s_{op} \gamma_X \frac{D_{\text{CO}_2}^0}{\tau} \quad [5]$$

where D_X^0 is the free-air molecular diffusion coefficient for gas X at the pressure and temperature of the site, τ is the tortuosity of the pore geometry and $\gamma_X = D_X/D_{\text{CO}_2}$ is the diffusivity of gas

X relative to that of CO_2 . Recommended values for γ_X are given in the supplement of Buizert et al. (2012). Although parameterizations of τ as a function of s_{op} do exist (Schwander et al., 1988), diffusivities measured on firn samples do not represent the diffusive behavior of the entire firn (Fabre et al., 2000). Best results are obtained when $\tau(z)$ is reconstructed site-specifically using measurements of reference tracers (see Section ‘Reconstructing the Effective Diffusivity’).

Diffusive transport leads to a separation of the gas mixture by gravity, resulting in a gradual enrichment in both heavy molecules and isotopologues with depth. In diffusive equilibrium, the enrichment relative to the atmosphere is given in delta notation by:

$$\delta_{\text{grav}} = \left[\exp\left(\frac{gz\Delta M}{RT}\right) - 1 \right] \times 10^3\text{‰} \cong \frac{gz}{RT} \Delta M \times 10^3\text{‰} \quad [6]$$

where ΔM can be the molar mass deviation from air in kg mol^{-1} ($\Delta M = M_X - M_{\text{air}}$) or the mass difference between two isotopologues when considering isotopic enrichment. Macroscopic transport processes, such as convection and advection, can locally drive the air column out of diffusive equilibrium, reducing the gravitational separation below the equilibrium slope given by eqn [6].

Temperature gradients in the firn also lead to diffusive separation of the gas mixture. Thermal diffusion results in seasonal isotope fractionation in the firn in response to the seasonal temperature cycle (Severinghaus et al., 2001; Weiler et al., 2009), as well as isotope excursions in the ice core record during abrupt climate changes (see Section ‘Thermal Fractionation and Gas Thermometry’). Thermal diffusion can be described as the tendency of heavier molecules to preferentially diffuse toward colder regions. This is illustrated in Figure 4 for firn air sampled at Siple Dome, Antarctica. The seasonal

Figure 4 Thermal fractionation by seasonal temperature gradients in the upper firn. Data are from Severinghaus et al. (2001); temperature measurements and firn air sampling were both done on 14 January 1998 at Siple Dome, Antarctica. Solid curves are a guide to the eye; the dashed line gives the equilibrium gravitational slope of eqn [6]. The $\delta^{40}\text{Ar}/^{36}\text{Ar}$ data have been divided by 4 to show the gravitational enrichment per unit mass difference.

temperature minimum around 5 m depth leads to a local enrichment in heavy isotopologues of N_2 and Ar.

Convection

In the firn air literature, convection is used as a generic term for processes that ventilate the upper firn, such as wind pumping (Colbeck, 1989), pressure variations due to seasonality and synoptic scale weather systems (Waddington and Cunningham, 1996), and convective flow driven by (seasonal) temperature gradients. Ventilation affects ice core and firn gas records, as well as postdepositional processes of volatile chemical species. The CZ is typically 1–15 m deep (Kawamura et al., 2006; Landais et al., 2006); an unusually thick CZ of 23 m was observed at the Megadunes site in central Antarctica, caused by a combination of strong winds and an accumulation hiatus giving rise to deep vertical cracks that act as conduits for air exchange (Severinghaus et al., 2010). CZ thicknesses are listed in Table 1. Typically, deep CZs are found at sites with low accumulation rates (e.g., Vostok) or high wind speeds (e.g., YM85). A clear negative correlation between accumulation rate and estimated CZ thickness was found along the EPICA Dome C deep ice core (Dreyfus et al., 2010).

The CZ thickness can be determined empirically using the barometric line-fitting method (Bender et al., 1994), in which the barometric slope is fit to isotopic data in the lower DZ, where the gravitational separation is undisturbed by temperature gradients and ventilation. The intercept with the depth axis gives the CZ thickness, as shown in Figures 3(c) and 4.

In numerical modeling of firn air transport, convection can be included in several ways. The most rudimentary way is to use the bottom of the CZ as the upper boundary and assume the air above to be of atmospheric composition. A more advanced approach is to include an eddy diffusion term that equally affects all gases and isotopologues (Kawamura et al., 2006):

$$D_{\text{eddy}}(z) = D_{\text{eddy}}^0 \exp\left(-\frac{z}{H}\right) \quad [7]$$

where D_{eddy}^0 is the eddy diffusivity at the surface and H is a characteristic depth scale. The eddy diffusion terms prevent gravitational separation by overwhelming molecular diffusion.

Advection

The bulk motion of air in the open porosity (see Section ‘Open Porosity Air Flow and Transport Properties’) gives rise to downward advective mass transfer of trace gases. Firn air models deal with advection in different ways. It can be included by dividing the firn column into boxes of equal air content, and shuffling them downward after a given time interval has elapsed (Schwander et al., 1993). An advantage of this approach is that it minimizes numerical diffusion artifacts. Alternatively, advection can be included as a continuous flux using a calculated air velocity in the open pores (Rommelaere et al., 1997; Sugawara et al., 2003). A third approach is to work in a Lagrangian reference frame that moves downward with descending ice layers (Trudinger et al., 1997). It must be noted that this approach overestimates the advective transport, unless the backflow due to pore compaction is explicitly taken into account.

Dispersive mixing

Equation [4] describes the average air velocity; in reality, a nonuniform velocity distribution exists between air expelled upward by pore compaction and air in isolated pockets, which is advected downward at the velocity of descending ice layers. Furthermore, atmospheric pressure variations and firn densification induce pressure gradients in the firn, which force viscous air flow. All these macroscopic flow patterns lead to dispersive mixing throughout the firn column, although it is overwhelmed by molecular diffusion in the DZ. Soil air studies have shown that viscous flow from atmospheric pressure fluctuations can induce mixing down to tens of meters, and that the dispersive flux can exceed the diffusive one (Massmann and Farrier, 1992). Firn air models do not explicitly include these flow patterns, and dispersive mixing is mostly neglected. Some studies include dispersion phenomenologically through an eddy diffusion term in the deepest firn (Buizert et al., 2012; Severinghaus et al., 2010).

Dating of Firn Air and Reconstructing Recent Atmospheric Composition

Reconstructing the Effective Diffusivity

Numerical firn air transport models are essential for dating and interpretation of firn air records. The largest uncertainty in the transport description is how the effective diffusivity of gases changes with depth (eqn [5]). Best results are obtained when the diffusivity profile is reconstructed through an inverse method (Rommelaere et al., 1997; Trudinger et al., 1997). The method consists of forcing a firn air model with a reference tracer of known atmospheric history (usually CO_2 or CH_4) and optimizing the fit to the measurements through adjusting the diffusivity profile. The procedure is illustrated in Figure 5(a) for the South Pole (SPO) and Northern Greenland Eemian Ice Drilling (NEEM) sites. The dashed line shows the modeled CO_2 -mixing ratio using the tortuosity parameterization of (Schwander et al., 1988). The solid lines show the fit to the data after the optimization procedure.

Several studies have used multiple reference tracers simultaneously to improve the diffusivity reconstruction (Buizert et al., 2012; Trudinger et al., 2002).

Age Distribution

Firn air does not have a single age, but is a mixture of air with different ages. Figure 5(b) shows for SPO how the CO_2 age distribution $G(z,t)$ progresses with depth. The mean age $\Gamma(z)$ of the gas mixture (first moment of the distribution) increases with depth, as the gases need time to be transported into the firn. Diffusion broadens the distribution with depth. Figure 5(c) compares age distributions at the bottom of the firn column for NEEM and SPO. The latter has a longer firn column and low accumulation rate, resulting in older air at the bottom of the firn as well as a wider distribution.

The gas age distribution, which is different for each gas, provides a complete description of the firn transport properties. Age distributions can be calculated by forcing a numerical firn air transport model at the atmospheric boundary with a

Figure 5 (a) Tuning procedure for transport modeling. Dashed lines show model solutions using the diffusivity parameterization of Schwander et al. (1988); solid lines show the optimized fit using CO_2 as a reference tracer. The Northern Hemisphere CO_2 seasonal cycle is clearly visible in the upper firn at NEEM. (b) CO_2 age distributions for selected depths at South Pole. (c) Comparison of NEEM and South Pole age distributions at the close-off depth (78 and 122 m, respectively). Top bars show the 95% age interval and mean CO_2 age.

rectangular pulse of short duration. Alternatively, they have been inferred experimentally by measuring the spread of the $\Delta^{14}\text{C}$ - CO_2 'bomb spike' caused by atmospheric testing of thermonuclear weapons, which peaks in the early to mid-1960s (Levchenko et al., 1996).

The gradual nature of the trapping process further broadens the age distribution. Air bubbles found at a single depth have not all been formed at the same time and represent a mixture of ages. Within the LIZ, where the majority of bubbles form, gas diffusivities are small and air in the open pores is advected downward at nearly the same velocity as the ice (Figure 3(b)).

Figure 6 Oxygen exchange between CO_2 and firn results in ^{18}O depletion with depth (lower axis). The dashed line shows the expected $\delta^{18}\text{O}$ signal in the absence of exchange; the solid line gives the best fit to the data based on the modeled ages (gray curve, upper axis) and the parameters listed. The reaction half-time $T_{1/2}$ is the only parameter that is tuned in the data fitting.

Consequently, the broadening due to trapping is small compared to the diffusive broadening described above (Blunier and Schwander, 2000).

Firn Air Dating with $\delta^{18}\text{O}$ of CO_2

An alternative firn air-dating method based on the isotopic composition of CO_2 has been presented by Clark et al. (2007). Atmospheric $\delta^{18}\text{O}-\text{CO}_2$ is relatively stable over time (Allison and Francey, 2007). Within the firn, atomic oxygen exchange with water molecules gradually alters the oxygen isotopic composition of CO_2 , until equilibrium with the strongly depleted $\delta^{18}\text{O}$ of glacial ice is reached (Siegenthaler et al., 1988). This principle is illustrated in Figure 6 for SPO firn.

Depending on the site temperature, the time required for the magnitude of the exchange to reach half its final magnitude ($T_{1/2}$) ranges from tens to hundreds of years depending on temperature (Assonov et al., 2005). Knowing the rate of O-exchange, the amount of time the CO_2 has been in contact with the ice (i.e., the age) can be calculated. The main advantage of the technique is its applicability to warm sites with summer melt layers that complicate conventional dating. The drawback is that $T_{1/2}$ and the equilibrium fractionation must be well known. Clark et al. (2007) solve this issue by using the $\Delta^{14}\text{C}-\text{CO}_2$ signal, which peaks around 1963, as an absolute age marker to calibrate $T_{1/2}$.

Reconstructing Recent Atmospheric Composition

The firn air itself preserves a continuous record of atmospheric composition which can be sampled to reconstruct trace gas-mixing ratios and isotopes for the recent atmosphere. Each firn

air sample represents a mixture of gas ages, and consequently mixing ratios measured in the firn cannot be directly mapped onto a timescale.

Once the firn air transport is well characterized using reference tracers, the forward diffusive problem is well described by the modeled age distribution alone. Subsequently, the most probable atmospheric history of a trace gas of interest can be reconstructed from firn air measurements through an inverse method (Rommelaere et al., 1997; Sugawara et al., 2003; Trudinger et al., 2002). For a more rudimentary dating, mixing ratios of a trace gas of interest can also be directly compared to reference gas measurements at identical sampling depths (Montzka et al., 2004).

Firn air has thus been used to reconstruct the recent atmospheric mixing ratios and/or isotopic composition of, for example, carbon dioxide (e.g., Etheridge et al., 1996), methane (e.g., Braunlich et al., 2001), ethane (Aydin et al., 2011), nitrous oxide (e.g., Ishijima et al., 2007), carbon monoxide (Assonov et al., 2007), several halocarbons (e.g., Butler et al., 1999; Sturges et al., 2001a), and carbonyl sulfide (e.g., Sturges et al., 2001b).

Effects of Firn Air Transport on Ice Core Records

The firn layer complicates the interpretation of ice core records as it alters the atmospheric composition prior to bubble closure. At the same time, the peculiarities of firn air transport give rise to additional signals that can be used for dating and climate reconstruction. In this section, we discuss the consequences of firn air transport for the interpretation of ice core records.

Delta Age and Gravitational Fractionation

Continued exchange with the atmosphere keeps firn air at the lock-in depth younger than the surrounding ice, resulting in an age difference Δage between glacial ice and the air bubbles it contains (Schwander and Stauffer, 1984). This is arguably the most important artifact of the firn layer. Accurate Δage estimates are pivotal in investigating the relative timing of abrupt changes in temperature and greenhouse gas concentrations (Barnola et al., 1991; Fischer et al., 1999), interhemispheric synchronization of ice core records (Blunier and Brook, 2001; Morgan et al., 2002), and deriving consistent ice core time-scales (Lemieux-Dudon et al., 2010). Figure 7 shows Δage estimates as a function of accumulation rate and temperature, assuming stationary conditions. The figure also indicates modern-day conditions of several firn-sampling and ice-coring sites.

The Δage is fixed at the lock-in depth, where gas diffusion effectively ceases and the stagnant air is advected downward with the ice. The modern-day Δage can be estimated accurately for sites that are well characterized using reference tracers; the largest uncertainty being the fraction of bubbles formed above the lock-in depth. To estimate Δage back in time, a combination of several methods can be used. First, past changes in lock-in depth can be estimated from accumulation and temperature variations, using firn densification models (Barnola et al., 1991; Goujon et al., 2003). Second, climatic changes recorded

Figure 7 Contour plot of Δage estimates as a function of temperature and accumulation rate. Indicated are modern-day conditions of several ice-coring sites. Density profiles were calculated using the steady state Herron-Langway model (Herron and Langway, 1980). Following Blunier and Schwander (2000), we assume gas lock-in at a density of 14 kg m^{-3} below the mean close-off density of eqn [1]. The age of the air was parameterized following Schwander et al. (1997).

in both the gas record and in precipitation stable isotopes allow determination of Δdepth (Figure 8), which in turn constrains Δage (Caillon et al., 2001, 2003; Severinghaus et al., 1998). Third, records of, for example, CH_4 or $\delta^{18}\text{O}-\text{O}_2$ from other well-dated ice cores, can be used for synchronization of chronologies (Capron et al., 2010; Loulergue et al., 2007).

The lock-in depth calculated by densification models can be compared to measurements of the gravitational enrichment in $\delta^{15}\text{N}-\text{N}_2$, which records the diffusive column length. Note that the diffusive column length does not directly give the lock-in depth, as the thickness of the CZ is unknown. Models predict a deeper lock-in depth during colder glacial conditions, implying a larger $\delta^{15}\text{N}-\text{N}_2$. This is indeed observed in Greenland ice cores (Schwander et al., 1997). Antarctic ice cores (with the exception of the coastal Byrd and WAIS-Divide sites) show a pronounced model-data mismatch with lower $\delta^{15}\text{N}-\text{N}_2$ (i.e., shorter diffusive column) during glacial conditions (Landais et al., 2006). An increased CZ thickness is often invoked to explain the mismatch, where the Megadunes site, with an unusually thick CZ of $>23 \text{ m}$, could provide a modern analog for central Antarctic glacial conditions (Severinghaus et al., 2010).

Measurements of gravitational enrichment in $\delta^{15}\text{N}-\text{N}_2$ are also used to correct gas records for the effect of gravity.

Thermal Fractionation and Gas Thermometry

Thermal diffusion causes isotopic fractionation in the presence of temperature gradients (see Section ‘Diffusion’). Seasonal temperature variations and the associated isotope effect occur

Figure 8 GISP2 oxygen isotopes of precipitation with 200-year running average (upper curve, left axis) and transient thermal fractionation signals in N_2 and Ar caused by rapid warming over Greenland (lower data, right axis). Data from Severinghaus et al. (1998) and Severinghaus and Brook (1999). The depth difference between the observed warming in the ice and gas records constrains Δage .

only in the upper firn (Figure 4). They could potentially affect the deep firn (and thereby the ice core record) through seasonality in transport properties, such as convective mixing and temperature-dependent diffusion coefficients. No evidence for such rectifier effects was found (Severinghaus et al., 2001); seasonal thermal fractionation should have little or no impact on the ice core record.

Climate-induced changes in mean annual surface temperature, on the other hand, can cause isotopic signals in the ice core record if the temperature change is sufficiently large and rapid. This principle is illustrated in Figure 8 for the GISP2 core in central Greenland. Abrupt warming events during the last deglaciation are accompanied by positive $\delta^{15}\text{N}$ and $\delta^{40}\text{Ar}$ excursions as the deep, colder firn gets enriched in heavy isotopes relative to the warmer surface. As the temperature sensitivity of $\delta^{15}\text{N}$ and $\delta^{40}\text{Ar}/4$ is different, the signals can be used in combination to infer the amplitude of the temperature change (Landais et al., 2004; Leuenberger et al., 1999; Severinghaus and Brook, 1999). The excursions furthermore provide clear time markers in the gas record that can be used to determine Δage more accurately than densification models allow. The method does not work well for Antarctica, where temperature changes are more gradual.

Molecular Size Fractionation at Close-Off

Within the LIZ, a systematic enrichment is observed for gas species with a small molecular diameter, such as He , Ar , Ne , and O_2 (Huber et al., 2006; Severinghaus and Battle, 2006). This has been explained by the preferential exclusion of these species from closing bubbles, causing them to accumulate in the open porosity. Closed bubbles are pressurized through continued firn compaction, which increases gas partial pressures in the bubbles relative to the open porosity. This gradient drives selective permeation of gas through the ice lattice. Huber et al. (2006) find a strong dependence of the fractionation magnitude on the collision diameter of the molecule, suggesting

Figure 9 Molecular size fractionation during bubble close-off, data and model output are from [Severinghaus and Battle \(2006\)](#). (a) Enrichment in O₂ and Ne versus N₂, expressed in delta notation using the modern atmosphere as the reference. Data are corrected for the effect of gravity. Note the slope in the DZ, indicative of a diffusive upward flux. (b) After δO₂/N₂ has been corrected for the atmospheric trend (mostly due to anthropogenic influence), there is a linear relation between δNe/N₂ and δO₂/N₂, indicating their preferential expulsion from closing bubbles occurs with a constant ratio.

a critical size of 3.6 Å. Recently, [Battle et al. \(2011\)](#) reported that the O₂ excluded from the closing bubbles is isotopically depleted in δ¹⁸O–O₂, showing the permeation through the ice lattice to be mass dependent. The mechanisms causing close-off fractionation are similar to those responsible for post-coring gas loss during ice sample storage ([Bender et al., 1995](#)).

The close-off fractionation is shown in [Figure 9](#) for SPO firn. The enrichment is strongest in the LIZ where the vast majority of bubbles are occluded, and the low effective diffusivity prevents diffusion of the signal. Note that a gradient exists in the DZ, indicative of an upward diffusive gas flux. Hereby some O₂ (Ne) is lost to the atmosphere, leading to a correspondingly depleted δO₂/N₂ (δNe/N₂) in gas bubbles.

It has been found that δO₂/N₂ can be used as a local summer insolation proxy, allowing orbital tuning of ice core chronologies ([Bender, 2002](#); [Kawamura et al., 2007](#)). This is thought to be controlled by a chain of events. Summer

insolation influences physical properties of surface ice grains, which in time will determine physical properties of deep firn strata after densification and metamorphism. [Bender \(2002\)](#) suggested that physical properties of grains near the firn–ice transition directly influence the magnitude of the O₂/N₂ fractionation. More recently, [Fujita et al. \(2009\)](#) proposed a model in which deep firn air transport is modulated, thus controlling the amount of O₂ lost to the atmosphere. Note that, though measured in the gas phase, δO₂/N₂ dating constrains the Ice Age and not the gas age.

Isotopic Diffusive Fractionation

A secular variation in the atmospheric mixing ratio of a gas species results in isotopic fractionation in the firn, even in the absence of a changing atmospheric isotopic composition ([Trudinger et al., 1997](#)). As an example, consider a rise in atmospheric CO₂. The lighter ¹²CO₂ isotopologue diffuses faster into the firn than ¹³CO₂, giving rise to isotopic depletion with depth. This diffusive fractionation can be approximated by

$$\varepsilon_{\text{DF}} = \begin{cases} -\frac{k}{C} \left(\frac{D}{D_i} - 1 \right) \Gamma(z) & \text{for } z \leq z_{\text{lid}} \\ -\frac{k}{C} \left(\frac{D}{D_i} - 1 \right) \Gamma(z_{\text{lid}}) & \text{for } z > z_{\text{lid}} \end{cases} \quad [8]$$

where C is the atmospheric mixing ratio (ppm), k the rate of increase (ppm year^{−1}), $D_i(D)$ the diffusion coefficient of the minor (major) isotopologue, Γ the mean gas age (year), and z_{lid} the lock-in depth.

[Figure 10](#) shows the diffusive fractionation calculated with eqn [8] and six numerical firn air models for a hypothetical exponential CO₂ increase of $k/C = 2.5 \times 10^{-3}$ (equivalent to $k = 1$ ppm year^{−1} at $C = 400$ ppm), while keeping δ¹³CO₂ fixed at 0‰. Within the DZ, the profiles agree well. Within the LIZ, the model solutions diverge, as the models use different parameterizations of LIZ transport. More work is needed to elucidate the nature of LIZ transport, and thereby the true magnitude of the diffusive fractionation.

Firn air and ice core records need to be corrected for the effect of diffusive fractionation, although often the effect will be small. Some corrections for the recent anthropogenic increase found in literature are 0.1‰ for ¹³CO₂ at Law Dome and 1.2‰ for ¹³CH₄ at WAIS-Divide ([Francey et al., 1999](#); [Mischler et al., 2009](#)). The effect is larger for CH₄ as the relative mass difference between the isotopologues, and thereby the ratio of diffusivities, is larger.

Smoothing by Diffusion and Bubble Trapping

The firn causes smoothing of the atmospheric signal, limiting the temporal resolution at which atmospheric variations are recorded in the ice. One can think of the firn as a low-pass filter to the atmospheric signal; high-frequency variations, such as the annual cycles of trace gases, are not preserved. [Spahni et al. \(2003\)](#) studied the attenuation of the rapid CH₄ excursion associated with the 8.2 ka event, and found it to be attenuated by about 13% in the GRIP core and 44% in the EPICA Dome C

Figure 10 Isotopic diffusive fractionation in the NEEM firn for a hypothetical atmospheric CO₂ scenario. See Buizert et al. (2012) for details and model acronyms.

Figure 11 Bode plot of the firn transfer function on a log–log scale (a) and semi-log scale (b), obtained by fast Fourier transform (FFT) of the modeled CO₂ age distributions halfway the LIZ. The transmitted signal amplitude is plotted as a function of the period of the oscillation ($P=1/f$ with f the frequency in year^{−1}).

core. The low accumulation rate and deeper lock-in depth at the latter site are responsible for the stronger attenuation.

By taking the Fourier transform of the age distribution, we can evaluate how atmospheric variations at different time scales are attenuated by the firn column (Figure 11). As the bubble trapping occurs predominately throughout the LIZ, the age distribution halfway the LIZ is taken as a measure of the signal recorded in the air bubbles. Additional smoothing by the trapping process is not accounted for. Atmospheric variations on time scales of several hundreds of years or longer are recorded with their full amplitude; variations faster than ~50 years are attenuated so strongly they cannot be observed within the measurement noise. Variations at intermediate time scales (such as the aforementioned 8.2 ka event) are recorded with reduced amplitude. In theory, the true atmospheric history could be reconstructed from high-resolution records with deconvolution techniques also used for water stable isotope records (Johnsen, 1977).

Summary

Firn air studies are important for interpretation of ice core gas records and reconstructing recent atmospheric variations. Following $\delta^{15}\text{N}-\text{N}_2$ gravitational enrichment, the firn column is divided in the convective, diffusive, and lock-in zones, where gas transport is dominated by surface ventilation, diffusion, and advection, respectively. Transport properties are determined by pore geometry and connectivity, as well as density layering. Diffusivity measurements on finite samples do not represent the entire firn, and diffusivity needs to be reconstructed using reference tracers. Gravitational separation, Δage , diffusive smoothing, and diffusive isotopic fractionation are firn effects that need to be considered when interpreting ice core records. Thermal fractionation and close-off fractionation give rise to new proxies that can be used for temperature reconstruction and dating.

Acknowledgments

The author would like to thank Mark Battle, Bruce Vaughn, and Todd Sowers for providing South Pole firn data, Thomas Blunier and Jakob Schwander for their careful review of the manuscript, and Maria Matos Nascimento in whose beautiful house on the Azores much of this work was written.

Long ice-core records from Africa are confined to the ice fields on the top of Kilimanjaro, which were drilled in 2000. Other glaciers such as the Lewis Glacier in Kenya and the Speke Glacier in Uganda have been investigated and their current retreat has been documented, but Kilimanjaro at 5893 m above sea level contains the highest and coldest ice fields on the continent, and thus, was determined to have the greatest potential to yield long, high quality records of climatic and environmental variation.

Located in northern Tanzania along its border with Kenya (**Figure 1(a)**), Kilimanjaro ($3^{\circ}04'S$, $37^{\circ}21'E$) is the highest mountain in Africa and the largest of a group of volcanoes that continued to be active until at least the end of the Pleistocene (**Downie and Wilkinson, 1972**). It is a massive and relatively undissected volcano, which rises 5895 m above sea level from a $95 \text{ km} \times 65 \text{ km}$ -wide base. Glaciers are believed to have existed on Kilimanjaro, as well as on Mount Kenya and in the Ruwenzori Range, throughout the Holocene (**Rosqvist, 1990**). In fact, glaciers existed on Kilimanjaro during several periods within the Quaternary, and evidence exists for three glaciations before 100 ka. This would suggest that no major eruptions have occurred in at least the last 500 ka.

A drilling program conducted in 2000 yielded six ice cores from three ice fields on the top of Kilimanjaro (**Thompson et al., 2002**). Kibo, the 2.5 km-wide caldera at the summit, contains several small ice fields (**Figures 1(b), 2(a), and 2(b)**), which are remnants of a former, more extensive glacier. Three ice cores were drilled on the largest, the Northern Ice Field (NIF), which was $\sim 50 \text{ m}$ thick in 2000. The Southern Ice Field (SIF), from which two cores were obtained, was $\sim 20 \text{ m}$ thick in 2000, while a small body of ice in the center of Kibo, the Furtwängler Glacier (FWG) was 10 m thick and was drilled

for one core. In addition, the remnants of the Eastern Ice Field are still visible, often as isolated thin spires of ice (**Figure 2(c)**).

Meteorology of Equatorial East Africa

The climate records from the Kilimanjaro ice cores reflect variations in monsoon intensity. The annual climatic regime over East Africa is very similar to that of southern Asia, where the surface airflow is determined by the position of the leading edge of a monsoon trough. Along the east coast of Africa, the intertropical convergence zone (ITCZ) moves southward from about 2°S in October to 12°S by the end of December. It remains in this extreme southern position until the end of January, then starts slowly back on its northern journey until the end of April, when it is again located at 2°S . At this stage, the wind convergence zone moves north of the equator and forces the southwest monsoon northwards. As the ITCZ moves southward and then northward, the rains also move with it. During its southward movement, rains occur over Kenya, Uganda, and Tanzania from mid-October to mid-December. This period is locally known as the season of 'Short Rains.' This area receives rain again from about mid-March to the beginning of June during the northward migration of the ITCZ, during the season of 'Long Rains' (**Asnani, 1993**). During the 'Short Rains,' northeasterlies and northerlies replace the southeasterlies in the lower troposphere along the west coast of Africa in association with the build-up of the anticyclonic ridge over the Arabian peninsula. During the 'Long Rains,' southeasterlies push from the south in the lower troposphere along the coast until the low-level jet is established by the end of June.

The Ice Core Records

Five of the six cores drilled were analyzed for stable isotopic ratios of oxygen (^{18}O and ^{16}O). Figure 3(a)–3(e) shows these records as 10-year averages ending at AD 1950, which is close to where a dated tritium signal was located (in 1951/52). The tops of the ice fields are rapidly disappearing; therefore, dating above the known chronology marker is difficult. Figure 3 shows the marked reproducibility of the climate signal from ice cores drilled from one end of Kibo to the other. The shortest

time series, that from the FWG (Figure 3(e)), indicates that its ice began accumulating around the middle of the seventeenth century, which was the beginning of the Maunder Minimum as well as a period of very high water levels in Lake Naivasha in Kenya (Verschuren et al., 2000; Figure 3(f)). This suggests that this small glacier in the middle of Kibo originated and grew during a pluvial phase in the East African climate history, which was also the onset of the coldest part of the recent neoglacial period, called the 'Little Ice Age.' This is also marked by ^{18}O depletion (more negative $\delta^{18}\text{O}$) in the records from the

Figure 3 Ten-year averages of isotopic ratios of ^{18}O – ^{16}O ($\delta^{18}\text{O}$) from (a) Southern Ice Field Core 1, (b) Southern Ice Field Core 2, (c) Northern Ice Field Core 3, (d) Northern Ice Field Core 2, (e) the Furtwängler Glacier, and (f) water levels from Lake Naivasha in Kenya over the last 1100 years (Verschuren et al., 2000; data archived at the World Data Center for Paleoclimatology, Boulder, CO, USA).

SIF and the NIF (Figure 3(a)–3(d)). The records from the SIF extend back to AD 500–700, suggesting that this ephemeral glacier began to form during this interval.

A high-resolution record of Holocene climate conditions for eastern Africa is provided by NIF Core 3 (NIF3). Fifty-year averages of soluble aerosols, insoluble dust, and $\delta^{18}\text{O}$ are shown for the past 11700 years (Figure 4). Lower aerosol values (chloride, nitrate, ammonium, potassium, magnesium, and sulfate) after ~1800 years ago suggest wetter conditions, which may have contributed to the accumulation of the SIF. The Kilimanjaro ice fields therefore appear to be sensitive to climatic changes in East Africa, responding relatively quickly to regional changes in effective moisture balances.

Major Climatic Events Recorded in the Kilimanjaro Record

The African Humid Period

During the African Humid Period (11–4 ka), generally warmer and wetter monsoon conditions prevailed in response to the precession-driven increase in solar radiation (Nicholson and Flohn, 1980; Street and Grove, 1979). Lakes in the region rose as much as 100 m above today's levels (Street-Perrott and Perrott, 1990). For example, Lake Chad expanded from 17000 km² to cover an area comparable to that of the Caspian

Sea today (Broström et al., 1998; Grove and Warren, 1968; Street and Grove, 1979). Calculations of the hydrological balance (Kutzbach, 1980) suggest that annual precipitation over the Lake Chad Basin was as high as 650 mm, compared with 350 mm today, and mean precipitation over the Ziway-Shala Basin in Ethiopia was also calculated to be 47% higher than today. The Magadi Natron basin on the border between Tanzania and Kenya contained a lake that was 50 m deeper than today and had an area of 1600 km² in the early Holocene (Hillaire-Marcel and Casanova, 1987). After ~4000 years, African lake levels dropped as conditions became cooler and drier.

In the ice-core record, the African Humid Period is documented by isotopic enrichment (less negative $\delta^{18}\text{O}$), at least until 6.5 ka, and lower concentrations of species such as magnesium, calcium, sulfate, and nitrate (Figure 4). Contemporaneously, fluoride and sodium were at their highest levels, which is interpreted as intermittent periods of rapidly fluctuating lake levels within the longer period of overall high lake stands. Sodium and fluoride rich alkaline volcanic rocks in the East African Rift Valley are the source for these anions (Hecky and Kilham, 1973), and when the rocks are weathered, the products that are deposited in lakes form fluoride salt crusts during evaporation, known as trona (Nanyaro et al., 1984), or

Figure 4 Fifty-year averages of concentrations of ion species and dust from NIF3, and stable isotopic ratios of ^{18}O – ^{16}O in NIF3 and NIF2. Abrupt climate events are marked by gray bars and events 1, 2, and 3 are discussed in the text.

magadi in the local vernacular. Periods of high runoff concentrate sodium and fluoride in the lakes, and when lake levels fall due to evaporation, trona precipitates and provides an aerosol source for the Kilimanjaro ice fields.

Abrupt climate events

Early Holocene

The fluoride concentrations between 8.4 and 8.2 ka are the highest in the Kilimanjaro record (marked as '1' in Figure 4), and are in fact the highest yet reported from any ice core. These high levels are nearly coincident with the large, abrupt reduction in methane (CH_4) in the European Greenland Ice Core Program (GRIP) core (Blunier et al., 1995), and with the largest ^{18}O depletion in the Holocene portion of both the GRIP and the Greenland Ice Sheet Project (GISP) 2 records (Alley et al., 1997). The peak fluoride and sodium levels suggest abrupt and intense lake level decreases accompanying a regional desiccation event. It is possible that the relatively short-term global CH_4 decrease was linked, and perhaps even preceded, by tropical hydrological changes leading to aridity, particularly in Africa.

Middle Holocene

An abrupt decrease in $\delta^{18}\text{O}$ from 6.5 to 5.3 ka ('2' in Figure 4), culminating in another sharp isotopic depletion at 5.2 ka, is

suggestive of a millennium-long climatic cooling. The interval of more negative ^{18}O values from 6.5 to 5 ka is nearly contemporaneous with a 'second humid period' (6.5–4.5 ka) when conditions were wetter than today, but drier than the early Holocene 'first humid period' (Nicholson and Flohn, 1980). During this time, the Ziway-Shala Basin attained its highest levels before dropping rapidly to near modern low levels by 4 ka (Street-Perrott and Perrott, 1990). The abrupt cooling event at the end of this second humid period about 5.2 ka is recorded as the largest ^{18}O depletion in the NIF record. This climatic change recorded in Kilimanjaro ice is contemporaneous with the largest ^{18}O enrichment in the Soreq cave speleothem record in Israel (Bar-Matthews et al., 1999), a decline in both lake levels in northern Africa (Sirocko et al., 1993; Street and Grove, 1976; Street-Perrott et al., 1990) and vegetative cover in India (Swain et al., 1983), and the lowest Holocene CH_4 concentrations in the GRIP ice core (Blunier et al., 1995). Documentary evidence ranging from northern Africa to Arabia (Weiss, 2000) also confirms this abrupt climate change. Around 5300 years ago, hierarchical societies formed in the Nile Valley and Mesopotamia, while Neolithic settlements in the inner desert of Arabia were abandoned (Uerpmann, 1990). This century-scale rapid cooling and drying event correlates with the Late Uruk abrupt climate change around 5.2 ka that is suggested to have altered environments outside the Mesopotamian lowlands (Weiss, 2000).

The second abrupt climate event recorded in the middle Holocene, dated around 4200 years ago ('3' in Figure 4), is associated with a visible dust layer (30 mm thick) and very high aerosol concentrations in NIF3. This is interpreted to represent a century-scale hiatus in ice accumulation due to a prolonged period of weaker monsoon activity. During this time, evidence indicates that the NIF decreased in size and that its southern ice wall retreated substantially. The $\delta^{18}\text{O}$ record from NIF2 actually begins at the chronological level of this event (Figure 4), which means that this part of the ice field began to reform only after the end of the drought. The ice field was most likely much larger by the end of the African Humid Period, but contracted very quickly during this dry interval. Thus, it appears that the major dust layer in NIF3 was formed during extremely dry conditions either before or during the retreat of the NIF margin.

This drought appears to have been widespread throughout the tropics, especially in those regions affected by monsoon circulation, and its climatic effects were experienced throughout northern and tropical Africa, the Middle East, and western Asia (Gasse and Van Campo, 1994; Pachur and Hoelzmann, 2000; Street-Perrott and Perrott, 1990). Water levels dropped in tropical east African lakes (Street-Perrott and Perrott, 1990), there was a very large influx of carbonate dust that was transported from Syria into the Gulf of Oman (Cullen et al., 2000), and the event is marked by a sharp increase in carbon isotopic ratios in the Soreq cave speleothem (Bar-Matthews et al., 1999). The drought was so severe that it has been considered instrumental in the collapse of a number of civilizations from North Africa to India (see articles in Dalfes

et al., 1997). The possibility that the drought extended beyond Africa, Asia and the Middle East into South America is suggested by the dust record in an ice core from the Andes of Northern Peru (Davis and Thompson, 2006). As the drought ameliorated, the NIF began to accumulate mass and reestablish itself over a larger portion of the crater rim.

Recent Retreat of East African Glaciers

All of the ice fields and glaciers in tropical East Africa are currently undergoing rapid retreat. Since ~1850 the Lewis Glacier on Mt. Kenya has decreased from 0.69 to 0.20 km², losing 71% of its surface area (Allison and Peterson, 1976), and from 1963 to 1992 alone it lost 40% of its mass (Hastenrath and Kruss, 1992). In fact a 1978 expedition to the Lewis Glacier, which sought to ascertain its suitability for drilling, confirmed that the ice was too warm (due to its low elevation and the recent warming) to preserve a useful climate record (Thompson, 1979). The surface area of the Speke glacier in the Ruwenzori Range in Uganda has decreased 74% from 6.51 km² in 1906 to 1.67 km² in 1990 (Kaser, 1998). Likewise, the ice cover on Kibo has retreated 85% (~12 to ~2.6 km²) from 1912 (Hastenrath and Greichar, 1997) to 2007 (Figure 5), and 26% of the ice that was present in 2000 has disappeared (Thompson et al., 2009). The ice on the Northern and Southern Ice Fields thinned about 3.6 and 24%, respectively from 2000 to 2007, while the ice on the FWG in the center of the crater thinned 50% from 2000 to 2009. At this rate, the FWG will disappear by 2018 and the remaining ice fields over the following decade, making the top of Kilimanjaro completely ice free for the first time in 11 ka.

There is no definitive consensus for the cause of the recent glacier retreat in East Africa. The discussion has been conducted in the scientific literature (e.g., Kaser et al., 2004; Mölg and Hardy, 2004; Mölg et al., 2009; Thompson et al., 2009, 2011) as well as in the media. The vertical lifting of the 0 °C isotherm resulting from increasing atmospheric warming has been cited, as has decreasing moisture in the region. The linear relationship, close to the meteoric water line, between $\delta^{18}\text{O}$ and deuterium isotopic ratios (δD) in the ice cores indicates that the disappearance of the ice fields on the top of Kilimanjaro is driven by melting (Thompson et al., 2011) rather than by sublimation (Cullen et al., 2007). In the Ruwenzori Mountains, which fall on the border between Uganda and D.R. Congo, both field work and satellite imagery show that the glaciers have decreased by ~50% in aerial extent from 1987 to 2003 (Taylor et al., 2006). This was synchronous with an increasing trend in air temperature of ~0.5 °C per decade over the last four decades. Limnological studies in this region confirm that the beginning of the modern glacier recession occurred with a warming regional climate and not with hydrological changes (Eggermont et al., 2010a,b; Russell et al., 2008). However, regardless of the cause(s), the disappearance of the ice fields in East Africa, particularly on Kibo, will have negative economic implications for the local populations as the ice is important for both the tourist industry and for the agricultural activities on the lower slopes.

Figure 5 Extent of the Kibo ice fields in 1912 (shaded) and 2007 (white). The 1912 ice extent is from Hastenrath and Greichar (1997), the 2007 ice extent is from Thompson et al. (2009).

Introduction

The Tibetan Plateau is defined by several mountain ranges that occupy the heart of central Asia (Figures 1 and 2). The plateau occupies an area extending roughly 2500 km (east–west) by 1000 km (north–south) and has an average elevation of over 4500 m above sea level (a.s.l.). The mountain ranges on the southern margin of the Tibetan Plateau – the Himalayas – contain the highest mountains in the world. Central Asian mountain ranges also contain a large number of glaciers (Figure 3) which together cover an area greater than 120 000 km² (Table 1), the highest concentration of glaciers outside of polar regions. A few of these glaciers provide sites that are suitable for the recovery of ice cores that extend back thousands of years and allow for the development of detailed records of climatic and environmental change in the region.

While the majority of ice-core investigations have been undertaken in the polar regions, chemical and physical analyses of ice cores recovered from carefully selected accumulation zones of central Asian glaciers allow for the development of detailed, high-resolution (i.e., seasonal to decadal) paleoclimate records. These records are especially important, given the critical role that the highlands of central Asia play in the development and intensity of the Asian monsoon, and the importance of the summer monsoon in providing life-sustaining rains to more than half the world's population. Central Asian ice cores provide records that document change in the monsoon on a variety of temporal and spatial scales. These records also provide the basis for the investigation of the linkages among the Asian monsoon and other coupled ocean–atmosphere circulation systems (e.g., El Niño/Southern Oscillation (SO) and the North Atlantic Oscillation (NAO)) as well as to assess possible forcing functions that cause climate to change and thereby improve our understanding of the Earth's climate system, especially at latitudes where the majority of Earth's human population live.

Asian Versus Polar Ice-Core Records

Compared to ice cores recovered from polar regions, the geographical setting of central Asian glaciers creates some additional challenges for the interpretation of central Asian ice-core records. First, while the relatively remote polar regions are distant from significant local sources of wind-blown dust, biogenic emissions, and anthropogenic emissions, central Asian glaciers lie adjacent to many of these large sources. For example, there are several large sources of wind-blown dust in central Asia which include the Taklamakan and Gobi deserts, and the arid regions east of the shrinking Aral Sea. This wind-blown dust is rich in calcium, magnesium, potassium, sodium, and chloride and is the dominant determinant of the spatial and seasonal variation of snow chemistry on most central

Asian glaciers (Wake et al., 1993, 2004). Glaciers which lie adjacent to large arid regions (such as those on the northern and western margins of the Tibetan Plateau) display very high concentrations of dust-related major ions, due to the influx of dust from local sources. Glaciers more distant from major dust source regions show intermediate levels of major ions and dust, while glaciers on the southern slopes of the eastern Himalayas are relatively free from the influence of desert dust (Figure 4). Anthropogenic emissions from Urumqi and the Indian subcontinent are also recorded in precipitation chemistry in the Bogda Shan and the Himalayas, respectively (Shrestha et al., 2002; Wake et al., 1992). In addition, biogenic emissions from agricultural activities in the Himalayas and southern Tibetan Plateau influence snow chemistry in the region (Kang et al., 2002c; Shrestha et al., 2002).

Second, the stable isotope measurements that have been central to the climatic records developed from polar ice cores do not necessarily provide a readily decipherable temperature proxy for central Asian ice cores. Several studies have shown that in the northern regions of the Tibetan Plateau, stable isotopes measured from individual precipitation events are well correlated with temperature as measured at nearby meteorological stations (Tian et al., 2003; Yao et al., 1996), and oxygen isotope records developed from ice cores in this region likely provide a proxy for temperature change, although the records are also influenced by changes in sources of moisture during different seasons or climatic periods (Hoffman and Heinmann, 1997; Kreutz et al., 2003). Stable isotopes measured in precipitation in the southern half of the Tibetan Plateau are influenced by the 'amount effect' and show the largest depletion of the heavier isotope (¹⁸O) during the summer (Figure 5; e.g., Kang et al., 2002a; Tian et al., 2003; Wushiki, 1977), and are also influenced by changes in source regions of moisture (e.g., Indian Ocean, Atlantic Ocean, Mediterranean Sea). These multiple influences on stable isotope ratios in precipitation in the Himalayas and southern Tibetan Plateau complicate the climatic interpretation of stable isotope records from this region and makes deciphering a proxy temperature signal difficult.

Third, several central Asian ice cores have been drilled in areas with significant meltwater percolation during the summer and in some cases, where accumulation occurs primarily as superimposed ice (ice exposed at the glacier surface that was formed by the refreezing of melted snow; commonly found in the accumulation area of a glacier). For example, at 5850 m on a small glacier on the south side of Nangapi Gosum in the central Himalayas, 20 m borehole temperatures were 0 °C and water was found in the borehole just below the firn–ice transition at 20 m. Stable isotope records show a seasonal signal for only the most recent year of accumulation: below this the seasonal signals have been homogenized as a result of meltwater percolation. Water was present in shallow boreholes drilled at 5350 m on the Fedchenko glacier in the Pamirs.

The effects of meltwater percolation have also been noted at 5180 m on Yala glacier (Watanabe et al., 1984). Despite this, glaciers in which melting occurs in the upper portion of the record do show seasonal signals and have provided valuable paleoclimate records discussed in detail below (e.g., Dundu, Guliya, Far East Rongbuk glacier), presumably because the melting is restricted to upper layers of central Asian glaciers in response to recent warming in the region (e.g., Liu and Chen, 2000).

Central Asian Ice Cores

Early Asian Ice Cores

Early efforts at recovering and analyzing ice cores from the mountains of central Asia began in the 1980s with a 60 m core recovered from the Yala glacier (5180 m a.s.l.), Nepal Himalayas (Watanabe et al., 1984), and a 17 m core recovered from the Sentik glacier (4908 m a.s.l.) in the Nun Kun massif in northwest India (Mayewski et al., 1984). Both cores were recovered in areas with relatively high snow accumulation (e.g., 0.9 m per year at Sentik) and were dated using the 1963

peak in total beta-activity resulting from the fallout of atmospheric nuclear weapons testing. Due to meltwater infiltration in summer, no seasonal signals were preserved in the Yala glacier core. Conversely, the Sentik core retained distinct seasonal layering and chemically differentiable shifts that were related to variability in monsoon circulation on seasonal to multiannual scales, indicating that climate-related records were preserved in at least some of the glaciers on the southern slopes of the Himalayas.

Deep Asian Ice Cores

Since the late 1980s, several long ice cores have been recovered from the mountains of central Asia (Table 2 and Figure 3) and provide records to investigate climate change on timescales ranging from decades to millennia. Three surface-to-bedrock cores were recovered from the Dundu ice cap on the north-east margin of the Tibetan Plateau in 1987 (Thompson et al., 1989). The $\delta^{18}\text{O}$, microparticle, and anion records developed from these cores provide a record of climate change for the northern regions of the Tibetan Plateau for the Holocene and late Pleistocene. The relatively high anion and microparticle

Figure 3 Location map for deep ice cores (>100 years of record) recovered from the mountains of central Asia. The heavy dashed line represents the 3000 m contour line and outlines the Tibetan Plateau. Landscape and topographic information were derived from a map (Tibet and the Mountains of Central Asia) published by the Royal Geographic Society (UK).

Table 1 Glacierized surface area in central Asia

Country	Area (km ²)
China	56 500
Pakistan and India	40 000
Kazakhstan, Tajikistan, and Kyrgyzstan	18 200
Nepal and Bhutan	7500
Afghanistan	4000

Figure 4 Variation of calcium concentrations (microequivalents per liter) in central Asian snow and ice with latitude. Details for data for each site provided in Wake et al. (1993, 2004). Note the very low calcium concentration on the southern slopes of the Himalayas (S. Himalayas) and the very high concentrations in the northern regions of the Tibetan Plateau.

Figure 5 Variation in mean $\delta^{18}\text{O}$ values in snow and precipitation by latitude from the northern Tibetan Plateau to the Himalayas. Period of record for each site ranges from 4 to 9 years over the time period 1991–99 (Tian et al., 2003). Note how the more southern locations have the most negative $\delta^{18}\text{O}$ value. This highlights the influence of the effect on $\delta^{18}\text{O}$ in precipitation in the Himalayas and the southern half of the Tibetan Plateau.
